7 Tear Gas (CS)¹

Acute Exposure Guideline Levels

PREFACE

Under the authority of the Federal Advisory Committee Act (FACA) P.L. 92-463 of 1972, the National Advisory Committee for Acute Exposure Guideline Levels for Hazardous Substances (NAC/AEGL Committee) has been established to identify, review, and interpret relevant toxicologic and other scientific data and develop AEGLs for high-priority, acutely toxic chemicals.

AEGLs represent threshold exposure limits for the general public and are applicable to emergency exposure periods ranging from 10 minutes (min) to 8 hours (h). Three levels—AEGL-1, AEGL-2, and AEGL-3—are developed for each of five exposure periods (10 and 30 min and 1, 4, and 8 h) and are distinguished by varying degrees of severity of toxic effects. The three AEGLs are defined as follows:

AEGL-1 is the airborne concentration (expressed as parts per million or milligrams per cubic meter [ppm or mg/m³]) of a substance above which it is predicted that the general population, including susceptible individuals, could experience notable discomfort, irritation, or certain asymptomatic, nonsensory effects. However, the effects are not disabling and are transient and reversible upon cessation of exposure.

AEGL-2 is the airborne concentration (expressed as ppm or mg/m³) of a substance above which it is predicted that the general population, including susceptible individuals, could experience irreversible or other serious, long-lasting adverse health effects or an impaired ability to escape.

AEGL-3 is the airborne concentration (expressed as ppm or mg/m³) of a substance above which it is predicted that the general population, including susceptible individuals, could experience life-threatening health effects or death.

Airborne concentrations below the AEGL-1 represent exposure concentrations that could produce mild and progressively increasing but transient and nondisabling odor, taste, and sensory irritation or certain asymptomatic, nonsensory effects. With increasing airborne concentrations above each AEGL, there is a progressive increase in the likelihood of occurrence and the severity of effects described for each corresponding AEGL. Although the AEGL values represent

threshold concentrations for the general public, including susceptible subpopulations, such as infants, children, the elderly, persons with asthma, and those with other illnesses, it is recognized that individuals, subject to idiosyncratic responses, could experience the effects described at concentrations below the corresponding AEGL.

SUMMARY

Tear gas is a white crystalline powder with a pepper-like odor. It was first synthesized by Corson and Stoughton in 1928 and is, thus, abbreviated as CS (Corson and Stoughton 1928; US Army Chemical School 2005). CS was developed in the 1950s as a replacement for the chemical incapacitant, 1-chloroacetophenone (CN), because CS was a much more potent irritant than CN, but was significantly less toxic (WHO 1970; Colgrave and Creasey 1975; Hu et al. 1989). It was adopted for use by the military, and was widely used in the Vietnam War (WHO 1970; Hu et al. 1989). It is currently used as an incapacitating agent both by military and law enforcement personnel (HSDB 2005). Upshall (1973) reported that an aerosol concentration of CS at 4 mg/m³ will disperse the majority of rioters within 1 min, and at 10 mg/m³ will deter trained troops. With the exception of more severe cutaneous reactions, recovery from exposure is generally rapid upon exposure to fresh air, generally within 30 min after exposure (Ballantyne 1977). CS may be manufactured through carbonyl condensation by combining *o*-chlorobenzaldehyde and malononitrile (HSDB 2005). Recent production data on CS were not found.

Human studies did not identify a no-effect level for CS or effects of CS that would be consistent with the definition of AEGL-1. The severity of the effects observed at the lowest tested concentrations in humans (ocular stinging and watering, and nasal, throat, and mouth irritation) exceeded those defined by AEGL-1. Therefore, AEGL-1 values for CS are not recommended. AEGL-2 values were based on human exposure to CS at an average concentration of 0.75 mg/m³ for 60 min (Beswick et al. 1972). All five subjects tolerated the exposure, but reported ocular stinging and watering, increased salivation, cough, and face stinging. Some subjects also reported throat irritation (4 subjects), nasal stinging and running (3 subjects), mouth stinging (2 subjects), chest burning (2 subjects), nausea (2 subjects), and headache (2 subjects). An intraspecies uncertainty factor of 3 was applied because contact irritation is a portal-of-entry effect and is not expected to vary widely among individuals. Furthermore, the responses of volunteers with jaundice, hepatitis, or peptic ulcer or who were 50-60 years old were similar to those of "normal" volunteers when exposed at a highly irritating concentration of CS for short durations. The ability to tolerate CS at 14-73 mg/m³ and the recovery time in volunteers with a history of drug allergies, seasonal allergies, asthma, or drug sensitivity were similar to normal volunteers; although more severe chest symptoms were reported in the people with pre-existing conditions (Gutentag et al. 1960; Punte et al. 1963). An interspecies uncertainty factor of 1 was applied because the study was conducted in humans. A modifying factor of 3 was also used because the effects observed at 0.75 mg/m³ were considered AEGL-2 effects. Time scaling was not performed because irritation is a function of direct contact with CS and is unlikely to increase

with duration of exposure at this level of severity (NRC 2001).

AEGL-3 values were based on calculated lethality thresholds for CS at each exposure duration. Rat data from the studies by [McNamara et al. \(1969\)](#), [Ballantyne and Callaway \(1972\)](#), and [Ballantyne and Swanston \(1978\)](#) were used calculate LC₀₁ (lethal concentrations, 1% lethality) values for CS. Calculations were performed using the probit analysis-based dose-response program of [ten Berge \(2006\)](#). Time scaling was performed using the equation $C^n \times t = k$, where the exponent n ranges from 0.8 to 3.5 ([ten Berge et al. 1986](#)). An empirical value for n of 0.70 was determined on the basis of the rat data. The 4-h AEGL-3 value was adopted as the 8-h AEGL-3 value because time scaling yielded an 8-h value inconsistent with the AEGL-2 values, which were derived from robust human data. A total uncertainty factor of 10 was applied. A factor of 3 was used to account for interspecies differences, because clinical signs are likely caused by a direct chemical effect on the tissues and this type of portal-of-entry effect is unlikely to vary greatly between species. Furthermore, calculated LCt50 values for different species were all well within a factor of 2 of each other (88,480 mg-min/m³ for rats, 67,200 mg-min/m³ for guinea pigs, 54,090 mgmin/m³ for rabbits, and 50,010 mg-min/m³ for mice) ([Ballantyne and Swanston 1978](#)). An uncertainty factor of 3 was used to account for intraindividual variability because contact irritation is a portal-of-entry effect and is not expected to vary widely among individuals. As noted above in support of the AEGL-2 values, a factor of 3 is also supported by the results of studies by [Punte et al. \(1963\)](#) and [Gutentag et al. \(1960\)](#) in subjects with pre-existing conditions.

AEGL values for CS are presented in [Table 7-1](#).

TABLE 7-1

AEGL Values for Tear Gas.

1. INTRODUCTION

CS is a white crystalline powder with a pepper-like odor. It was first synthesized by [Corson and Stoughton](#) in 1928 (thus, the abbreviation CS) ([Corson and Stoughton 1928](#); [US Army Chemical School 2005](#)). It was developed in the 1950s as a replacement for the chemical incapacitant, 1-chloroacetophenone (CN), because CS was a much more potent irritant than CN, but was significantly less toxic ([WHO 1970](#); [Colgrave and Creasey 1975](#); [Hu et al. 1989](#)). CS was adopted for use by the military, and was widely used during the Vietnam War ([WHO 1970](#); [Hu et al. 1989](#); [Smith and Greaves 2002](#)). It is currently used as an incapacitating agent by military and law enforcement personnel ([HSDB 2005](#)). It is reported that an aerosol concentration of 4 mg/m³ will disperse the majority of rioters within 1 min, and 10 mg/m³ will deter trained troops ([Upshall 1973](#)). With the exception of more severe cutaneous reactions, recovery from exposure is generally rapid upon exposure to fresh air, usually within 30 min after exposure ([Ballantyne](#)

1977).

Because CS is stable when heated and has a low vapor pressure, it requires a means of dispersment (Blain 2003). Different forms of dispersment include the combination of CS with a pyrotechnic compound in a grenade or canister, generating a smoke or fog, and dispersment of a fine powder as an aerosol (WHO 1970; Smith and Greaves 2002). CS1 is a micronized powder formulation of CS containing 5% silica gel for dissemination by an explosive burst or dusting apparatus, and CS2 is the same as CS1 except that the CS1 is microencapsulated with silicone to improve its weather resistance and flow properties (WHO 1970).

In controlled studies investigating the toxicologic properties of CS aerosol, CS was disseminated as a 2-10% solution in methylene chloride or acetone by means of a pneumatic atomizing nozzle assembly (Gutentag et al. 1960; Owens and Punte 1963; Punte et al. 1963) or by thermal dispersion by spraying the molten chemical (Gutentag et al. 1960; Punte et al. 1962, 1963).

CS may be manufactured through carbonyl condensation by combining *o*-chlorobenzaldehyde and malononitrile (HSDB 2005). Recent production data of CS were not available.

Hydrolysis of CS produces malononitrile and *o*-chlorobenzaldehyde (NTP 1990). Hydrolysis of CS is relatively rapid, with a half-life of about 15 min at a pH 7, but CS reacts faster with an alkaline solution, having a half-life of about 1 min at a pH of 9 (Blain 2003).

CS has a vapor pressure of 3.4×10^{-5} mm Hg; thus, at concentrations greater than 0.35 mg/m^3 , it will exist in vapor and aerosol forms. CS in the vapor phase will be degraded by reaction with photochemically produced hydroxyl radicals, with an estimated half-life of 110 h. CS in the particulate phase will be removed by wet and dry deposition.

The chemical and physical properties of CS are presented in Table 7-2.

2. HUMAN TOXICITY DATA

2.1. Acute Lethality

No human acute lethality data on CS were found.

2.2. Nonlethal Acute Toxicity

2.2.1. Experimental Studies

In a review article, Blain (2003) reported a TC50 (concentration that caused a perceptible effect

on 50% of the population exposed for 1 min) of 0.004 mg/m³ for ocular irritation and 0.023 mg/m³ for airway irritation. An ICT50 (concentration intolerable to 50% of the population exposed for 1 min) was also reported. No further details were presented.

A group of male volunteers was exposed to CS aerosol with a mass median diameter (MMD) of 0.9 microns (94 ± 15 mg/m³; 4% larger than 10 microns) or up to 60 microns (85 ± 16 mg/m³; 4% smaller than 20 microns) to assess differences in ocular and respiratory responses to different particle sizes of CS (Owens and Punte 1963). Six volunteers who had the best ability to tolerate CS were chosen from a group of approximately 50. Subjects wore tightly fitted goggles and a nose and mouth respirator designed to protect against particle sizes less than one micron, and were exposed individually in a wind tunnel with a constant air speed of 5 mph. The exposure protocol was designed to restrict exposure to either the small or large particles to the eyes, to the respiratory system, or to both the eyes and respiratory system. The wind tunnel was elevated to a height of 5 feet, and a rubber-lined port was installed in the bottom of the duct enabling the subject to insert his head into the airstream of the tunnel and remove it quickly after the exposure. CS was disseminated from a 2% solution in methylene chloride by means of a pneumatic atomizing nozzle assembly. CS concentrations were determined from air samples collected using filter paper placed on air sampling probes located around the head area (one on top and one on each side at eye level), followed by extraction with ethanol and measurement with ultraviolet spectrophotometry. A modified cascade impactor was used to measure the CS aerosol containing the small particles, while the larger particles were sized microscopically, measuring and counting the various particles in the pre-ground material before dissemination. Tolerance time was defined as the time at which a subject could no longer remain in the atmosphere containing the compound and left the exposure chamber, and recovery time was defined as the time after the exposure when the subjects were able to sort and arrange a series of 24 playing cards from which the corner numbers were removed. Control values were determined before each test. The results indicate that small particles are more effective in rapidly producing ocular irritation (see Table 7-3). The onset of ocular response is hypothesized to be faster with small particles because of they are more soluble than larger particles in ocular fluid. Once begun, however, the irritation process would continue for a longer period with the large particles compared with the small particles. Respiratory effects were more severe with small particles (no volunteers could withstand exposure for more than 30 seconds [sec]) and required more time for recovery than the large particles. The difference in response is due to the ability of smaller-sized particles to penetrate more deeply into the respiratory tract. When both the eyes and the respiratory system were exposed to CS, the respiratory response predominated with exposure to the small particles, whereas the ocular response predominated with exposure to the large particles.

microns).

A group of 4-6 volunteers was exposed to CS aerosol in a wind tunnel (8 × 8 × 8 feet; fixed wind speed of 5 mph) (Gutentag et al. 1960; Punte et al. 1963). Volunteers were both military and civilian personnel. Each volunteer's medical history was recorded, and each was given pre-exposure and post-exposure physical examinations. Volunteers were classified as "normal" or were placed in one of four special categories: those with hypertension (diastolic pressure of 80-110 mm Hg or normal blood pressure reading with a history of hypertension; pre-exposure tests included electrocardiogram, chest X-ray, liver function, and urinalysis); those with hay fever, drug sensitivity, or bronchial asthma (volunteers with asthma had normal chest X-ray before exposure); those with a history of jaundice, hepatitis, or peptic ulcers without gastrointestinal bleeding; and those that were 50-60 years of age. Subjects classified as normal were further categorized into untrained men with or without protective masks or trained men with or without protective masks. The trained men had previous exposure to CS, whereas the untrained men did not. CS was dispersed as a 10% solution in acetone or methylene dichloride with a spray nozzle (MMD 3.0 or 1.0 micron, respectively) or by thermal dispersion (spraying the molten chemical; MMD 0.5 micron). Airborne samples of the aerosol were collected at various points in the wind tunnel. Particle size was characterized using a 6-stage modified cascade impactor, and exposure concentrations were measured using ultraviolet spectrophotometry. The subjects did not report any noticeable difference in symptoms from the different dispersion methods.

Groups of 3-6 untrained men without masks were exposed to CS in acetone, and tolerance times were recorded. Times ranged from 53 to >120 sec at 5 mg/m³, 19-43 sec at 12 mg/m³, and up to 5 sec at 442 mg/m³. When groups of 1-7 trained men were exposed, tolerance times ranged from 37 to >120 sec at 4 mg/m³, 18-41 sec at 10 mg/m³, and up to 12-25 sec at 141 mg/m³. To compare the effects of hyperventilation on symptoms, untrained subjects ran for approximately 100 yards before exposure. Exercising subjects could not tolerate CS as well as normally breathing subjects; groups of three subjects exposed at 10, 13, or 39 mg/m³ could tolerate CS for up to 13, 13, and 9 sec, respectively. While ocular irritation was minimal, chest symptoms were more pronounced and recovery time was slightly prolonged (by 1-2 min). The reactions of subjects with jaundice, hepatitis, or peptic ulcer or those that were 50-60 years old were similar to those of normal subjects. Subjects with a history of drug allergies or sensitivities, hay fever, or asthma also tolerated exposure to CS at concentrations comparable to those tolerated by normal subjects, but the group with pre-existing conditions had a higher percentage of individuals with more severe chest symptoms, with many of them laying prostrate on the ground for several minutes. However, no wheezing or rhonchi were heard, and recovery was as rapid as that seen in other exposure groups. When subjects were exposed to CS at temperatures ranging from 0-95°F,

tolerance to the chemical was slightly reduced at the high temperature of 95°F. Whether the decrease in tolerance was an actual effect of the exposure, the uncomfortable climate, or a combination of both was unclear. An increase in skin-burning symptoms with increased temperature was attributed to an increase in perspiration.

As part of the study described above, the potential for developing tolerance to CS was investigated by exposing a group of four subjects to CS at 1.5 mg/m³ for 90 min in a 20,000-L chamber (Punte et al. 1963). No data were provided about the monitoring of the CS aerosol. During exposure, subjects were allowed to smoke, read, and play cards. Only one subject reported nasal irritation (after 2 min), three subjects reported headaches (after 45, 50, and 83 min), and all four subjects reported ocular irritation (after 20, 24, 70, and 75 min). In the second part of the experiment, the four subjects were exposed to CS at 1.5 mg/m³ for 40 min, and then additional CS aerosol was added to the chamber to achieve an airborne concentration of 11 mg/m³ in about 10 min. Although the subjects had not been told of the increase in concentration, they all left within 2 min due to respiratory irritation. The exposure concentration was estimated to be 4.3-6.7 mg/m³ when the subjects left the chamber. In the third part of the experiment, the subjects were exposed to CS at 6 mg/m³, which was attained over 10 min. Symptoms reported by the subjects included nasal and throat irritation, chest burning, sneezing, ocular irritation and lacrimation, headache, and dermal irritation. Three of the four subjects reported that the exposure was unbearable after 18, 20, and 29 min, with chest symptoms being the reason the subjects left the chamber. The remaining subject was able to tolerate the agent, and the exposure was terminated after 40 min. The investigators attempted to enter the chamber without the benefit of the gradual increase in exposure concentration, and were unable to remain in the chamber. In the fourth experiment, a concentration of 6.6 mg/m³ was attained over 30 min. The usual signs and symptoms of CS exposure developed, but to a lesser degree. One of the subjects had to leave after 2 min because of a violent cough, but he returned to the exposure chamber after his cough had ceased upon exposure to fresh air. He remained in the exposure chamber for the duration of the 60-min exposure.

To assess the potential effect of CS exposure on ventilation, cardiac frequency, and breathing pattern, a group of 11 healthy soldier volunteers was exposed to CS aerosol (particle diameter of 1 micron) at a concentration that was progressively increased from 0.2 mg/m³ to 1.3 mg/m³ (Cotes et al. 1972; Cole et al. 1977). The exposure duration was not specified, but appeared to be approximately 80 min. CS aerosol was produced by saturating the exposure chamber the evening before the exposure, followed by flushing with air to remove all of the gas except that adsorbed onto the walls and equipment. During exposure, pyrotechnic generators were ignited to progressively raise the concentration of CS throughout the exposure session. Subjects wore woolen or denim battle dress covered with cotton coveralls, boots, and gaiters. Electrocardiogram electrodes were applied to the chest, and subjects wore a full respirator into the chamber. For the commencement of exposure, each subject removed his own respirator.

During each exposure, each subject completed two 8-min periods of exercise, which consisted of cycling at 20W up to 120W. During exercise, the subjects breathed through an oral-nasal mask and three-way valve box. Inspiration was from the chamber and expiration was through a 6-L capacity mixing bottle into a low resistance gas meter. Cardiac frequency was measured by electrocardiograph, while a thermister in the valve box recorded respiratory frequency. A control exposure including exercise was conducted the day before and the day after exposure to CS. A major difference between the control and CS exposures was that ventilation was continued throughout the control session but not the CS-exposure session; therefore, the temperature was much higher during the CS-exposure sessions than the control session ($\sim 24^\circ$ vs. 20.5°C for controls).

All subjects experienced intense discomfort, including cough, lacrimation, and substernal pain, when first exposed to the CS aerosol. Discomfort was severe enough that two subjects withdrew (one before and one after the first period of exercise), and two additional subjects were unable to complete the first period of exercise due to coughing. Coughing coincided with ignition of the CS generators. The discomfort disappeared with continuing exposure. Although cardiac frequency increased during exposure to CS compared with control air, the difference was eliminated when the cardiac frequency was corrected for the increased ambient temperature (corrected to the arbitrary temperature of 20°C). The ventilation minute volume was reduced from exposure to CS compared with controls. The reduction appeared to be due to a decrease in respiratory frequency. The exposure was repeated using 17 volunteers (Cole et al. 1975, 1977). Exposure conditions were the same with the following exceptions: the CS candles were ignited between and not during periods of exercise, CS concentrations were slightly higher ($0.92\text{-}2.15\text{ mg/m}^3$), and the subjects were seen on five consecutive half-day sessions (the first, third, and fifth sessions were for control observations and the other two sessions were allocated one each for exposure to ammonia and to CS [the order of exposure changed between the different weeks of the study]). Results were generally the same as those observed in the first study. The only difference was that the reduction in the ventilation minute volume was the result of a diminution in tidal volume and occurred despite an increase in respiratory frequency.

To investigate the potential for developing tolerance to CS, 35 healthy male volunteers were exposed for 60 min to increasing concentrations of CS aerosol (Beswick et al. 1972). Exposures were conducted in a 100-m^3 chamber. The chamber was generally saturated an hour before the exposure, followed by air being blown through the chamber to remove the CS not absorbed on the walls and equipment. A number of parameters were assessed before and after exposure, including chest radiograph results, hematology and clinical-chemistry analysis, and respiratory-function tests to assess peak flow, tidal volume, and vital capacity. A total of 10 exposure trials were conducted, with no volunteers exposed more than once. Exposure concentrations were kept relatively constant in the first three trials: $0.53\text{-}0.86\text{ mg/m}^3$ in trial 1 (three subjects), $0.71\text{-}0.78\text{ mg/m}^3$ in trial 2 (five subjects), and $0.31\text{-}0.74\text{ mg/m}^3$ in trial 3 (six subjects). For the seven

remaining trials, exposure concentrations were increased by a factor of 2, 3, or 4 during the exposure period: 0.8-1.4 mg/m³ in trial 4 (five subjects), 0.84-2.3 mg/m³ in trial 5 (four subjects), 0.7-2 mg/m³ in trial 6 (four subjects), 0.63-2.3 mg/m³ in trial 7 (two subjects), 0.57-2.1 mg/m³ in trial 8 (two subjects); 0.42-1.8 mg/m³ in trial 9 (two subjects), and 0.45-1.7 mg/m³ in trial 10 (two subjects). Chamber concentrations were measured at 10-min intervals. Volunteers entered the chamber wearing full respirators and protective coveralls. CS was generated and allowed to mix for 3 min before removal of the respirator. Symptoms from all volunteers were reported during individual interviews after exposure. The results of the 10 trials were consolidated into five groups: group I included trial 2 (five subjects), group II included trials 1 and 3 (nine subjects), group III included trial 4 (five subjects), group IV included trials 5 and 6 (eight subjects), and group V included trials 7, 8, 9, and 10 (eight subjects). One of the six subjects in trial 3 left the exposure chamber after 8 min of exposure with complaints of severe stinging of the eyes, throat irritation, cough and dyspnea, salivation, and nausea, and one subject in group IV left after 55 min due to vomiting. All other subjects remained in the chamber for the entire 60-min exposure period. A summary of the symptoms of the exposed individuals is presented in [Table 7-4](#). The predominant symptoms included excess production of mucus and saliva (34/34 subjects), ocular irritation (stinging in 32/34 subjects and lacrimation in 32/34 subjects), runny nose (28/34 subjects), and face stinging (32/34 subjects). Symptoms generally resolved within 10 min of leaving the chamber. Nausea was reported by 11/34 subjects and two vomited, which appeared to follow swallowing of large amounts of saliva. The development of tolerance was assessed in two of the trials (group IV in [Table 7-4](#)); in these trials, half of the subjects removed the respirator at the start of the exposure (with the CS concentration increasing with time), while the remaining subjects did not remove their respirators until the last 5 min of exposure. The subjects that were exposed to CS throughout the entire exposure period were able to withstand the entire 60-min exposure (concentrations increasing from 0.84 to 2.30 mg/m³ and 0.70 to 2.00 mg/m³) except for the one individual that had to leave the chamber at 55 min because of vomiting. Of the subjects that removed their respirators for the last 5 min of exposure, only one of eight subjects could remain in the chamber for more than 1 min; five left within 30 sec of removing their respirators. No exposure-related changes were observed in hematology or clinical chemistry parameters. Decreases in heart rate after exposure ceased were ascribed to the sense of relief each volunteer felt at the end of an uncomfortable experience, and the increase in systolic blood pressure observed in individuals when exposure commenced was due to the abrupt onset of discomfort; continued exposure resulted in normal blood pressure readings. No abnormalities were noted in measurements of respiratory function, but the investigator noted that the sample size was small and, thus, may not be representative. It was concluded that the main effects of CS are due to local irritation of exposed nerve endings, and systemic changes noted are due to stress.

Symptoms of Volunteers Exposed to Tear Gas for 60 Minutes.

Three groups of volunteers were exposed to CS aerosol at various concentrations to investigate potential effects on visual acuity (Rengstorff 1969). The first group was composed of 10 male volunteers exposed to CS₂ aerosol (CS treated with Cab-o-Sil[®] 5 and hexamethyldisilaxane) at concentrations of 0.1 to 1.7 mg/m³. The exposure was conducted in a wind tunnel suspended 4.5 feet above the floor; the volunteer sat on a chair at the end of the wind tunnel and put his head through a rubber aperture in the tunnel until he could no longer tolerate the exposure or for a maximum of 10 min. A powder dispenser disseminated specific concentrations of CS₂ (MMD of 0.8 microns) into the air at a wind speed of 4.5 mph. An Orthorater was used to measure the binocular far and near visual acuity of the subjects before and after exposure. The second and third groups were exposed to CS aerosol in a circular steel chamber. CS aerosol (MMD of 0.9 micron) in a methylene dichloride solution was disseminated using a thermal generator, and introduced into the chamber as a uniform cloud. Subjects wore protective masks for the first 5 min in the chamber, and then removed their masks for the commencement of exposure. The second group was composed of 34 volunteers, and an Orthorater was again used to measure the binocular far and near visual acuity before and after exposure. A summary of the amount of time volunteers from this group could tolerate exposure to CS is presented in Table 7-5. The third exposure involved 22 volunteers who had a baseline visual acuity of 20/20 and who could remain in the exposure chamber for 10 min. Binocular acuity was measured using a Snellen visual acuity projector before, during, and a few minutes after exposure. The Snellen chart contained a row of 20/30, 20/25, and 20/20 letters. No exposure-related changes in visual acuity were noted except those due to the inability of some subjects to keep their eyes open because of intense ocular irritation. Visual acuity returned to normal in all subjects several minutes after exposure to CS ended.

TABLE 7-5

Tolerance of Humans Subjects Exposed to Tear Gas for Up to 10 Minutes in Study Evaluating Visual Acuity.

To assess the effect of CS exposure on respiration, a group of six volunteers (four with previous exposure to CS) were exposed to various concentrations of CS (3 micron) in a wind tunnel while a portable breathing device monitored respiration (Craig et al. 1960). Subjects remained in the tunnel until the exposure became intolerable (see Table 7-6). Notable coughing was observed in subjects exposed at 15 mg/m³ for 61 sec or at 150 mg/m³ for 12 sec. On the basis of the recordings made during exposure, it was concluded that although the breathing pattern of the volunteers was disrupted, adequate ventilation was maintained. Therefore, the incapacitation of

CS is attributed to the unpleasant sensations of exposure rather than to any degree of respiratory failure.

TABLE 7-6

Tolerance of Human Subjects Exposed to Tear Gas in Study
Evaluating Respiratory Effects.

A group of 38 US Marines was exposed to a cloud of CS dispersed by a thermal canister as part of a training exercise to test the ability and speed of the trainees in donning their gas masks (Thomas et al. 2002). The exposure occurred after 6 days of strenuous training with minimal sleep and reduced food consumption, and was followed by a 1.5-mile run. Temperature and relative humidity at the time of exposure were approximately 24°C and 91%, respectively. Clinical signs and symptoms began to develop 36-84 h post-exposure during and after periods of strenuous exercise (one subject became symptomatic after a 1,000-meter pool swim at 36 h post-exposure; seven became symptomatic after a second swim consisting of a 1,000-meter open ocean swim 60 h post-exposure; and one became symptomatic after a third swimming event consisting of a 1,500-meter open ocean swim 84 h post-exposure). A total of nine subjects were affected, with four requiring admission into intensive care. Effects of exposure included dyspnea upon exertion, hemoptysis (ranging from frank blood to blood-tinged sputum), cough, rales, reduced arterial blood gas (range of 60-68), and infiltrates visible on chest radiograph. Signs and symptoms resolved by 72 h, and lung function before and after exercise challenge returned to normal within 1 week post-exposure. When the exposure in this study was recreated (without test subjects) and air sampling was performed, CS concentrations were found to range from less than quantifiable to approximately 17 mg/m³.

McDonald and Mahon (2002) proposed that the pulmonary symptoms in the Marines described in the study by Thomas et al. (2002) were not the result of CS exposure, but were rather the result of water aspiration or swimming-induced pulmonary edema (SIPE). Their conclusions were based on the observations that all subjects became symptomatic immediately after swimming, that there was a rapid resolution of symptoms, and that there was no evidence of airway dysfunction. Delayed pulmonary effects of CS exposure are unusual, and there were no other reports of such symptoms even though approximately 200,000 Marines have been exposed to CS since 1996 under similar field conditions.

2.2.2. Case Reports

The effects of exposure to CS are generally of an acute nature. However, reactive airways dysfunction syndrome was reported in two individuals exposed to CS. One case involved a healthy 21-year-old female exposed to CS smoke at a nightclub for 5-10 min (Hu and Christiani 1992). She exhibited the typical signs and symptoms of CS exposure, including tightness and

burning in her chest and coughing. Results of a physical examination and chest radiography were normal, and she was released from the hospital. She continued to experience coughing and shortness of breath, and had reduced measurements of forced expiratory volume in 1 sec (68% of predicted) and forced vital capacity (78%) 4 weeks after exposure. Cough and shortness of breath were still present at the 2-year follow-up exam, and were made worse by exertion, cold air, and some environmental pollutants. The second case report involved exposure to a riot-control agent containing 1% CS and 1% oleo resin capsicum (Roth and Franzblau 1996). A healthy 53-year-old male was exposed for at least 30 sec, and immediately experienced symptoms of mucous membrane irritation, cough, and chest tightness. Wheezing and shortness of breath continued for months after exposure, and were severe enough to require hospitalization. Pulmonary function test results indicated reversible and fixed obstructive pulmonary disease. Effects of exposure to the capsicum cannot be excluded.

A 4-month-old infant exposed to CS for 2-3 h developed pneumonitis and persistent leukocytosis (Park and Giammona 1972). The infant was exposed when a CS canister was fired into a house to subdue an adult. Upon hospitalization, the infant had copious nasal and oral secretions and was sneezing and coughing. A chest X-ray demonstrated that the lungs were clear, but laboratory testing revealed leukocytosis. The infant developed severe respiratory distress by the second day of hospitalization, with pulmonary infiltrates evident on X-ray by day 7. Pulmonary infiltration began to decrease on day 15, and the lungs were clear on day 17. White blood cell counts were elevated throughout hospitalization, and finally decreased when the infant was discharged from the hospital.

CS is a common riot-control agent in Britain; consequently, typical symptoms following exposure to CS have been described following its use in confined spaces, such as a night club (Breakell and Bodiwala 1998) or bus (Karagama et al. 2003), use by police on individuals for self-defense (Euripidou et al. 2004), or under conditions of large-scale riot control (Himsworth 1969; Anderson et al. 1996). Symptoms of exposure included but were not limited to ocular irritation, lacrimation, blurred vision, burning sensations sometimes accompanied by first degree burns, cough, headache, shortness of breath, chest pain, sore throat, retching, vomiting, and salivation (Himsworth 1969; Anderson et al. 1996; Breakell and Bodiwala 1998; Karagama et al. 2003; Euripidou et al. 2004). In general, the symptoms resolved rapidly; however, there were reports of effects lasting longer than that predicted. The hand-held spray canisters used by police contain CS dissolved in methyl isobutyl ketone, an industrial solvent and denaturant (Gray 2000; Euripiou et al. 2004). It has, therefore, been proposed that the ketone combined with the CS may result in longer lasting adverse effects than CS preparations without the solvent.

2.3. Developmental and Reproductive Toxicity

The National Teratology Information Service collected outcome data on 30 pregnant women who were exposed to CS gas: 12 women during the first trimester, 11 during the second trimester, and

seven during the third trimester (McElhatton et al. 2004). Acute maternal toxicity (transient symptoms of ear, nasal, and throat irritation) was reported by 50, 82, and 57% of the exposed women, respectively. Pregnancy outcome was not adversely affected by exposure to CS. Birth weight was within the normal range except for one female baby weighing less than 2,500 g. One infant had a congenital anomaly (hypospadias), and this anomaly has a background incidence of 1 in 1,000 live born male infants. No concentration or duration exposure parameters were described.

2.4. Genotoxicity

No data on the genotoxicity of CS in humans were found.

2.5. Summary

CS is a potent irritant, with symptoms of exposure including lacrimation, blepharospasm, erythema of the eyelids, chest tightness, coughing, nasal irritation and discharge, salivation, throat irritation, nausea, vomiting (from swallowing excess saliva), and cutaneous irritation (ranging from stinging to contact irritation or allergic dermatitis). Upshall (1973) reported that an aerosol concentration of CS at 4 mg/m³ will disperse the majority of rioters within 1 min, and 10 mg/m³ will deter trained troops. With the exception of more severe cutaneous reactions, recovery from exposure is generally rapid upon exposure to fresh air, generally within 30 min after exposure (Ballantyne 1977).

Data on human tolerance to CS are summarized in Table 7-7. Many studies investigated the amount of time that elapsed before subjects could no longer remain in an atmosphere containing CS. Gutentag et al. (1960) and Punte et al. (1963) reported tolerances of 5 sec at 442 mg/m³, 12-25 sec at 141 mg/m³, 9 sec at 39 mg/m³, and more than 90 min at 1.5 mg/m³. Tolerance to low concentrations of CS could be increased when exposure concentration was increased over time (Punte et al. 1963; Beswick et al. 1972). A study investigating the differences in respiratory and ocular responses to different particles sizes of CS found that small particles are more effective than larger particles in producing ocular and respiratory irritation. Recovery time for ocular irritation took longer for large particles, because the onset of irritation was delayed due to the lower solubility of large particles. Recovery time for respiratory irritation took longer for small particles, because the smaller sized particles penetrated further into the respiratory tract (Owens and Punte 1963).

Concentration (mg/m ³)	Exposure Time (min)	Observations
442	5	Subjects showed inability to inhale CS
141	12-25	Subjects showed irritation of eyes, nose, and throat
39	9	Subjects showed irritation of eyes, nose, and throat
1.5	>90	Subjects showed irritation of eyes, nose, and throat

TABLE 7-7

Summary of Selected Human Toxicity Data on Tear Gas.

Pregnancy outcomes were not affected in a prospective case study of 30 pregnant women who

were exposed to CS gas and experienced transient symptoms of ear, nasal, and throat irritation (McElhatton et al. 2004). No other reproductive or developmental toxicity data of CS in humans were available. No human data on the toxicity of repeated exposures to CS or on the genotoxicity or carcinogenicity of CS were found.

3. ANIMAL TOXICITY DATA

3.1. Acute Lethality

3.1.1. Monkeys

Groups of eight immature male and female *Macaca mulatta* monkeys (3-4 kg) were exposed to a cloud of CS dispersed via an M7A3 CS grenade in a 20,000-L chamber at an average CS concentration of 900 mg/m³ for 3 min, 1,700 mg/m³ for 5 min, 2,850 mg/m³ for 10 min, or 2,500 mg/m³ for 32 min (Striker et al. 1967). The report stated that the cloud was sampled and measured at various times, but details were not provided. A group of eight monkeys served as controls; they were treated similarly to the exposed monkeys except they were not put into an exposure chamber. Monkeys were observed frequently for clinical signs during the first 72 h after exposure. Chest radiographs were taken before exposure and after 2, 6, or 12 h or 1, 3, 7, or 30 days post-exposure. Monkeys were killed after 12 h or after 3, 7, or 30 days. Clinical signs in monkeys exposed to CS at 900 mg/m³ for 3 min or at 1,700 mg/m³ for 5 min included blinking and a “fright reaction” observed immediately after removal from the exposure chamber, which disappeared within a few minutes after the monkeys were moved to fresh air. Monkeys exposed at 2,850 mg/m³ for 10 min exhibited frequent blinking, labored respiration, coughing, oral and nasal discharge, occasional vomiting, and decreased activity and response to external stimuli. One monkey also had copious ocular discharge. Clinical signs were most severe at 12 h and were generally resolved within 72 h. Clinical signs in monkeys exposed to CS at 2,500 mg/m³ for 30 min were severe and included prostration, dyspnea, copious oral and nasal discharge, and scleral congestion after removal from the exposure chamber. Five monkeys died; four died 3-12 h after exposure and one died on day 4. Dyspnea was most severe at 12 h, while oral and nasal discharge and effects on the eyes were most severe at 24 h. Radiographic findings were present only in this group; infiltrates appeared 3 h after exposure, were most severe after 24 h, and cleared after 3 days.

Pathologic examination of the monkeys 12 h after exposure to CS at 900 or 1,700 mg/m³ revealed mild pulmonary congestion, bronchorrhoea, emphysema, and atelectasis (Striker et al. 1967). These effects disappeared in the monkeys examined on day 3, but recurred in monkeys examined on days 7 and 30. Pathologic lesions were more severe and developed earlier in monkeys exposed at 2,850 mg/m³ for 10 min. Pulmonary edema and congestion and bronchorrhoea were found at 12 h, and progressed to purulent bronchitis and bronchopneumonia at day 3. After 1 week, acute pleuritis and interstitial pneumonitis were seen, and mucosal lesions

and bronchopneumonia were resolving. Lesions were still present after 4 weeks, and included emphysema, atelectasis, and focal interstitial pneumonitis. Pathologic findings in monkeys that died after exposed to CS at 2,500 mg/m³ for 30 min included severe pulmonary edema and congestion. The three surviving monkeys were killed on days 3, 7, or 30. The monkey killed on day 3 days had considerable edema, but congestion was less prominent. Examination of the monkey killed on day 7 revealed emphysema involving all lobes and bronchiolitis, but most of the edema had cleared. The monkey killed on day 30 had small shrunken lungs, purulent mucoid material filling many small bronchioles, and distinct bronchiolitis.

McNamara et al. (1969) exposed groups of four monkeys (strain and sex not specified) to seven different CS concentration-duration combinations. No further experimental details were available. Mortality data from this study are summarized in [Table 7-8](#).

Species	Concentration (mg/m ³)	Duration (min)	Mortality	Time to Death (days)
Monkey	500	30	0/4	0/4
	1000	30	2/4	0/4
	2500	30	2/4	0/4
	5000	30	2/4	0/4
	10000	30	2/4	0/4
	25000	30	2/4	0/4
Rat	1000	30	0/10	0/10
	2500	30	0/10	0/10
	5000	30	0/10	0/10

TABLE 7-8

Mortality Data from Studies by McNamara et al. (1969) in Different Species Exposed to Tear Gas.

3.1.2. Rats

Groups of 10 rats were exposed to an aerosol of CS for 25-90 min (Punte et al. 1962). Animals were exposed in a dynamic inhalation chamber containing individual cages on racks. Aerosol was generated by passing dry nitrogen through an aspirator. Molten CS was maintained in a side-armed flask in an oil bath at 140-150°C. The aerosol was easily generated and liquid droplets recrystallized before entering the exposure chamber. Chamber concentrations were measured by drawing chamber air through filter paper for subsequent analysis by spectrophotometry. Samples for particle-size determinations were collected by a Cascade impactor, and MMD was derived by use of stage calibrations based on the density of the compound; the particle size was about 1.5 microns (MMD). Observations for clinical signs were made during and after exposure. Surviving animals were maintained for 14 days, and then killed and examined histopathologically. Immediately after exposure began, the animals became excitable and hyperactive, and lacrimation and salivation occurred within 30 sec. Lethargy and dyspnea occurred after approximately 5-15 min. Dyspnea persisted for approximately an hour after exposure ceased, and all other signs subsided about 5 min after the rats were removed from the chamber. Histopathologic examinations revealed an increase in the number of Goblet cells in the respiratory tract and conjunctiva, necrosis in the respiratory and gastrointestinal tracts only if particles had impacted the surface, and an occasional animal with pulmonary edema and hemorrhage in the adrenal glands. The calculated LCT50 was 32,500 mg-min/m³.

An unpublished report by McNamara et al. (1969) appears to provide data additional to those that were published by Punte et al. (1962). Specific study details are not provided in the unpublished report, but one set of study results is consistent with those published by Punte et al.

(1962). The report includes the mortality results from tests with additional animal species exposed by inhalation to CS, as well as mortality data for CS dispersed by different methods. As discussed above, Punte et al. (1962) reported mortality data for rats, but the values were reported only in terms of $\text{mg}\cdot\text{min}/\text{m}^3$. Specific concentrations of CS (sprayed as molten agent) with corresponding exposure durations for these data are reported in the unpublished study by McNamara et al. (1969) and are presented in Table 7-8.

Groups of 18 male albino SPF rats were exposed to pyrotechnically-generated CS smoke in a 10-m^3 chamber (Colgrave and Creasey 1975). The rats were exposed to at $5,871 \pm 476 \text{ mg}/\text{m}^3$ for 15 min, at $6,030 \pm 590 \text{ mg}/\text{m}^3$ for 10 min, or at $6,800 \pm 1,166 \text{ mg}/\text{m}^3$ for 5 min (averages and standard deviations were calculated on the basis of the values reported by the investigators as 6,000, 6,000, and 6,400 mg/m^3 , respectively). CS was released from four CS cartridges, each containing CS (12.5 g), potassium chlorate (16 g), lactose (15 g), and kaolin (7.5 g). The cloud of CS in the exposure chamber was sampled at approximately 1-min intervals for the 10- and 15-min exposures and at 30-sec intervals during the 5-min exposure. The analytic method used to measure CS concentrations was not described. Survivors were killed at times ranging from 15 min to 2 days post-exposure. All animals were necropsied, and selected tissues were analyzed by both light and electron microscopy. Nonexposed controls were used to establish the typical macroscopic and microscopic appearance of the tissues of the particular strain used. Mortality occurred in four rats exposed at $5,871 \text{ mg}/\text{m}^3$ for 15 min (death occurred with 24 h), and in two rats exposed at $6,030 \text{ mg}/\text{m}^3$ for 10 min (death occurred within 24 or 36 h). All animals exposed at $6,800 \text{ mg}/\text{m}^3$ survived until the study terminated after 2 days. Animals that died after exposure to CS for 15 min developed marked pulmonary congestion with scattered alveolar hemorrhages and patchy edema. Survivors developed less marked pulmonary congestion and only occasional areas of edema and hemorrhaging. Rats that died after exposure to CS for 10 min also developed pulmonary congestion, but the severity was much less than that seen with the 15-min exposures. Hemorrhages and edema were occasionally seen in the lungs of survivors. Examination of rats exposed to CS for 5 min revealed mild pulmonary congestion with occasional hemorrhage up to 6 h post-exposure. Rats killed between 12 h and 2 days post-exposure had no pulmonary findings except for one rat with moderate and extensive pulmonary congestion. Electron microscopic examination of the lungs from all exposed rats revealed changes in the epithelium and interstitium, with accumulation of fluid between the membrane layers and collagen-containing areas of the septum. Degenerative changes of the epithelium and endothelium led to rupture or dissolution of the capillary wall. The investigators stated that the changes were similar in all exposed rats, with the changes varying only in the degree of severity. Damage was evident as early as 15 min after exposure, and became more severe after 30 and 60 min.

Ballantyne and Callaway (1972) exposed groups of male and female Wistar-derived SPF rats to pyrotechnically-generated CS smoke at concentrations of $750 \text{ mg}/\text{m}^3$ for 30 min, $480 \text{ mg}/\text{m}^3$ for 1 h, or $150 \text{ mg}/\text{m}^3$ for 2 h in a 10-m^3 exposure chamber. A group of control animals was also

maintained, but no description of the treatment of the controls was provided to determine whether they were exposed under similar conditions to clean air. The grenades used for the exposure contained CS (2 g), potassium chlorate (2.4 g), lactose (2.4 g), and kaolin (1.2 g). Although the report stated that the concentration of CS in the exposure chamber was sampled at the start of the exposure and at 6-min intervals up to and including 57 min, no information was provided about the analytic technique. Groups of animals were killed after 1, 10, and 28 or 29 days. Some of the animals exposed at 480 or 150 mg/m³ were retained for up to 32 months to evaluate potential lasting toxicity and pathology (Marrs et al. 1983a). Animals that died or were moribund after 1 month and those killed after 32 months were subjected to gross necropsy, and the heart, lungs, small intestine, liver, pancreas, spleen, kidneys, brain, gonads, and pituitary and adrenal glands were removed and processed for histologic examination.

All animals exposed for 30 min at 750 mg/m³ survived to the scheduled necropsy, and histopathologic changes were found only on post-exposure day 1 (see Table 7-9). One rat had congestion of alveolar capillaries and a few scattered alveolar hemorrhages, while another rat had a few minute foci of renal tubular necrosis at the inner cortex. No pathologic changes were found in rats at post-exposure day 10 or 28. Exposure to CS at 480 mg/m³ for 1 h resulted in the mortality of some rats (see Table 7-9), with the majority of the deaths occurring on post-exposure days 1 and 2. Pathologic changes in animals surviving exposure at 480 mg/m³ were generally confined to post-exposure day 1; lesions were limited to minimal pulmonary congestion and hepatic congestion in one rat, minimal pulmonary hemorrhage and hepatic necrosis in another rat, and mild pulmonary congestion in a third rat. Two rats had mild pulmonary edema. A few rats killed after 10 days had healed lesions, as evidenced by binucleate liver cells around centrilobular veins and immature epithelium in some renal tubules. No abnormal pathologic changes were noted at day 29. Histopathologic findings in rats that died were much more severe and included renal changes (mild-to-moderate necrosis of the cortex, moderate-to-severe necrosis of the medulla, and some mild congestion), pulmonary changes (mild-to-severe congestion, mild hemorrhage, and some mild edema), and hepatic changes (glycogen depletion in all rats and a few cases of mild congestion and mild-to-moderate necrosis).

Dose (mg/m ³)	Species	Sex	Day 1		Day 10		Day 28

TABLE 7-9

Summary of Acute Toxicity Data from Studies by Ballantyne and Callaway (1972) in Hamsters and Mice Exposed to Tear Gas.

Exposure to CS at 150 mg/m³ for 2 h resulted in no mortality. Pathologic examination of the animals revealed lesions only on day 1 post-exposure. Lesions were confined to female animals; one rat had a few scattered alveolar hemorrhages, one had acute mucoid enteritis, and one had pneumonic consolidation of the upper right lung lobe.

The resultant aerosol was fed into the diluting air stream. The chamber atmosphere was sampled for 1 min at 5-min intervals by aspirating air through glass fiber discs held in double cone filters. A bubbler containing hydrochloric acid in ethanol was connected in line to the glass filter to act as an additional trap. The contents of the bubbler were used to elute CS from the filter discs, and the concentration of CS in the resultant extract was measured by absorption spectrophotometry and compared with a prepared standard. Signs of toxicity included increased nasal and buccal secretions and increased rates of respiration when removed from the chamber; effects disappeared within approximately 1 h post-exposure. No animals died during exposure; deaths generally occurred within the first 2 days following exposure. A summary of mortality data is presented in [Table 7-11](#). Necropsy findings in animals dying within 48 h included pulmonary congestion and edema (with some animals also having multiple variable sized hemorrhages) and congestion of the trachea. Moderate amounts of mucus were also seen in the trachea. Histopathologic examination of the lungs from these animals revealed moderate-to-marked congestion, inter- and intra-alveolar hemorrhaging, and excess secretions in the bronchioles and intrapulmonary bronchi. Examination of animals dying after 48 h revealed similar findings, as well as evidence of early bronchopneumonia. Congestion of the liver, kidneys, spleen, and small intestines were also frequently seen in animals dying from exposure. No abnormal findings were found in animals surviving the 14-day observation period.

Species	Average Concentration (mg/m ³)	Exposure (min)	Mortality (%)	Mortality (No. dead/No. exposed)
Rats	1,000	30	0	0/10
	1,000	45	0	0/10
	1,211	45	0	0/10
	2,421	45	100	10/10
	2,421	60	100	10/10

TABLE 7-11

Summary of Mortality Data from Studies by Ballantyne and Swanson (1978) in Different Species Exposed to Tear Gas.

3.1.3. Mice

Groups of 20 mice were exposed to an aerosol of CS for 10-60 min (Punte et al. 1962). Experimental procedures, clinical signs, and necropsy results are similar to those described for the corresponding study in rats (see [Section 3.1.2](#)). The calculated LCT50 was 43,500 mg-min/m³. An unpublished report by [McNamara et al. \(1969\)](#) appears to provide data additional to those that were published in this study. Specific study details are not provided in the unpublished report, but one set of study results is consistent with those published by [Punte et al. \(1962\)](#). The report includes the mortality results from tests with additional animal species exposed by inhalation to CS, as well as mortality data for CS dispersed by different methods. [Punte et al. \(1962\)](#) reported mortality data for mice, but the values were reported only in terms of mg-min/m³. Specific concentrations of CS (sprayed as molten agent) with corresponding exposure durations for these data are reported in the unpublished study by [McNamara et al. \(1969\)](#) and are presented in [Table 7-8](#).

[Ballantyne and Callaway \(1972\)](#) exposed groups of 10 mice for 5-20 min to CS at an approximate concentration of 4,000 mg/m³, followed by a 14-day observation period. The

experimental protocol, clinical signs, and necropsy findings were similar to those described in the corresponding study in rats (see [Section 3.1.2](#)). Mortality data are summarized in [Table 7-10](#).

Groups of 19-40 male albino mice were exposed by whole body inhalation to various concentrations of CS aerosol for 15-30 min (see [Table 7-11](#)) ([Ballantyne and Swanston 1978](#)). The experimental protocol, clinical signs, and necropsy findings were similar to those described in the corresponding study in rats (see [Section 3.1.2](#)). Mortality data are summarized in [Table 7-11](#).

3.1.4. Guinea Pigs

Groups of ten guinea pigs were exposed to an aerosol of CS for exposure durations of 5-40 min ([Punte et al. 1962](#)). Experimental procedures, clinical signs, and necropsy results are similar to those described for rats in [Section 3.1.2](#). The calculated LCT50 is 8,300 mg min/m³. An unpublished report by [McNamara et al. \(1969\)](#) appears to provide data additional to those that have been published. Specific study details are not provided in this report, but one set of study results is consistent with those published by [Punte et al. \(1962\)](#). The report includes the mortality results of additional animal species exposed by inhalation to CS, as well as mortality data for CS dispersed by various methods. As described above, [Punte et al. \(1962\)](#) reported mortality data for guinea pigs, but the values were reported only in terms of mg min/m³. Specific concentrations of CS (sprayed as molten agent) with corresponding exposure durations for these data are reported in [McNamara et al. \(1969\)](#) and are presented in [Table 7-8](#).

[Ballantyne and Callaway \(1972\)](#) exposed groups of five guinea pigs for 5 to 20 min to an approximate CS concentration of 4,000 mg/m³, followed by a 14-day observation period. The experimental protocol, clinical signs, and necropsy findings are similar to those described in the rat study (see [Section 3.1.2](#)). Mortality data are summarized in [Table 7-10](#).

Groups of ten to twenty female Dunkin Hartley guinea pigs were exposed by whole body inhalation to various concentrations of CS aerosol for durations of 10 to 45 min (see [Table 7-11](#)) ([Ballantyne and Swanston 1978](#)). Experimental protocol, clinical signs, and necropsy findings are as described for the rat study in [Section 3.1.2](#). Mortality data are summarized in [Table 7-11](#).

3.1.5. Rabbits

Groups of four rabbits were exposed to an aerosol of CS for exposure durations of 30-90 min ([Punte et al. 1962](#)). Experimental procedures, clinical signs, and necropsy results are similar to those described for rats in [Section 3.1.2](#), except that hyperactivity, salivation, and lachrymation were not reported. The calculated LCT50 is 17,000 mg min/m³. An unpublished report by [McNamara et al. \(1969\)](#) appears to provide data additional to those that have been published. Specific study details are not provided in this report, but one set of study results is consistent with those published by [Punte et al. \(1962\)](#). The report includes the mortality results of

additional animal species exposed by inhalation to CS, as well as mortality data for CS dispersed by various methods. As described above, Punte et al. (1962) reported mortality data for guinea pigs, but the values were reported only in terms of mg min/m^3 . Specific concentrations of CS (sprayed as molten agent) with corresponding exposure durations for these data are reported in McNamara et al. (1969) and are presented in Table 7-8.

Ballantyne and Callaway (1972) exposed groups of five rabbits for 5 to 20 min to an approximate CS concentration of $4,000 \text{ mg/m}^3$, followed by a 14-day observation period. The experimental protocol, clinical signs, and necropsy findings are similar to those described in the rat study (see Section 3.1.2). Mortality data are summarized in Table 7-10.

Groups of five to ten female New Zealand white rabbits were exposed by whole body inhalation to various concentrations of CS aerosol for durations of 5 to 60 min (see Table 7-11) (Ballantyne and Swanston 1978). Experimental protocol, clinical signs, and necropsy findings are as described for the rat study in Section 3.1.2. Mortality data are summarized in Table 7-11.

3.1.6. Hamsters

Ballantyne and Callaway (1972) exposed groups of male and female golden hamsters to pyrotechnically-generated CS smoke at concentrations of 750 mg/m^3 for 30 min, 480 mg/m^3 for 1 h, or 150 mg/m^3 for 2 h in a 10-m^3 exposure chamber. The experimental protocol is the same as that for the corresponding study in rats (see Section 3.1.2). All animals exposed for 30 min at 750 mg/m^3 survived to the scheduled necropsy, and histopathologic changes were observed only on post-exposure day 1 (see Table 7-11). Three hamsters had a few scattered alveolar hemorrhages, and one also had congestion of the alveolar capillaries. No pathologic changes were found at post-exposure day 10 or 28. Exposure at 480 mg/m^3 for 1 h killed some hamsters (see Table 7-11); the majority of the death occurred after 1-2 days. Pathologic changes in animals surviving exposure at 480 mg/m^3 were generally found only on post-exposure day 1. Eight hamsters had mild pulmonary congestion, and four of them also had mild pulmonary hemorrhage. One hamster with no lung lesions had mild renal congestion and necrosis in the medulla, and another had mild necrosis in the medulla. A few hamsters killed after 10 days had healed lesions, as evidenced by binucleate liver cells around centrilobular veins and immature epithelium in some renal tubules. No abnormal pathologic changes were found at day 29. Histopathologic findings in hamsters that died were generally similar to those in rats (see Section 3.1.2); however, the lesions were less severe in hamsters than in rats.

Exposure to CS at 150 mg/m^3 for 2 h resulted in the mortality of two male hamsters (after 12 or 16 days), and necropsy revealed bronchopneumonia. Pathologic examination of surviving animals revealed lesions only on day 1. Lesions were found only in female hamsters; one had a few scattered alveolar hemorrhages and two had a few scattered foci of acute renal tubular necrosis at the inner cortex.

Exposure to CS at 480 mg/m³ for 1 h or at 150 mg/m³ for 2 h did not affect the lifespan of the hamsters, and no statistically significant increases in non-neoplastic lesions were found in the exposed groups compared with controls (Marrs et al. 1983a). Common non-neoplastic lesions in male and female hamsters included changes in the lungs (engorgement, congestion, inflammatory changes, and pulmonary edema) and pyelonephritis of the kidneys. No exposure-related neoplastic lesions were evident in male or female hamsters.

3.1.7. Dogs

McNamara et al. (1969) exposed groups of four dogs (strain and sex not specified) to eight different CS concentration-duration combinations. No further experimental details were available. Mortality data are summarized in Table 7-8.

Following a 30-sec exposure to CS at 25 mg/m³, one dog exhibited increased blood pressure, an altered respiratory pattern, tachycardia, and increased femoral artery blood flow (Cucinell et al. 1971). In another test, two dogs were exposed for 23 min to CS at 2,600 mg/m³. One dog survived and the other dog died after 52 h. The investigators noted that dogs recover partially when exposed to a lethal dose of CS but then develop respiratory distress and die within 48-70 h.

3.2. Nonlethal Acute Toxicity

3.2.1. Mice

An RD₅₀ (concentration that reduces the respiratory rate by 50%) for CS of 4.0 mg/m³ (95% confidence interval: 3.3-5.2 mg/m³) was reported for male Swiss-Webster mice (Kane et al. 1979).

3.2.2. Rabbits

To investigate whether CS exposure can cause diarrhea, four rabbits were exposed to thermally-generated pure CS in a 10-m³ chamber (Ballantyne and Beswick 1972). The exposures involved the following: one rabbit each was exposed at 58 mg/m³ for 30 min, 46 mg/m³ for 20 min, 54 mg/m³ for 12 min, or 17 mg/m³ for 17 min. Animals were placed singly in cages with removable trays lined with several layers of filter paper arranged to collect stool samples. The number of stool pellets passed, their total weight, and their water content were recorded for several day before and after exposure. Exposure to CS did not result in an increased incidence of diarrhea.

Two rabbits were exposed in a static chamber to the entire contents of a 3-ounce unit containing 71.5 g of CS (Gaskins et al. 1972). The unit required 20 sec to fully dispense. Both rabbits became unconscious after approximately 2 min of exposure and were moved to fresh air. The rabbits regained their righting reflex approximately 10-20 min after exposure and were almost completely recovered after 1 h (moderate ocular wetness was the only visible effect). Gross necropsy of the rabbits performed after 2 weeks did not reveal any abnormalities. Two other

rabbits were exposed to 23.2 g of CS during dispersion of a CS unit requiring about 10 sec to completely discharge. The dispensed CS formed a cloud in the chamber. The rabbits tried to avoid the spray as it was dispensed, and then sat quietly with their eyes tightly closed for the remainder of the 5-min exposure. No abnormalities were observed in the eyes or skin of the rabbits.

3.3. Repeat-Dose Studies

3.3.1. Rats

Groups of five male and five female F344/N rats were exposed to CS₂ at concentrations of 0, 1, 3, 10, 30, or 100 mg/m³ for 6 h/day, 5 days/week for 2 weeks (NTP 1990). (CS₂ contains 94% CS, 1% hexamethyldisilazane, and 5% Cab-o-Sil[®]). All rats exposed at 30 or 100 mg/m³ died before the end of the study. Rats from all exposure groups exhibited adverse clinical signs, ranging from erythema and blepharospasm at the lower concentrations to dacryorrhea, mouth breathing, listlessness, and mouth breathing at the higher concentrations. Rats in the 1-mg/m³ group gained more weight over the exposure period than controls, but at concentrations of 3 mg/m³ and higher body weight was generally decreased.

Groups of 10 male and 10 female F344/N rats were exposed to CS₂ at 0, 0.4, 0.75, 1.5, 3, or 6 mg/m³ for 6 h/day, 5 days/week for 13 weeks (NTP 1990). One male rat exposed at 6 mg/m³ died, and all others survived to study termination. Clinical signs of ocular irritation (partial or complete eyelid closure) were noted in all exposure groups, and rats exposed at 6 mg/m³ developed erythema of the extremities that persisted overnight. Rats exposed to CS₂ at 1.5 mg/m³ or higher gained significantly less weight over the study period than controls; final mean body weight was 17-44% lower than that of controls for males and 10-24% lower for females. An approximate 46% reduction in thymus weight relative to body weight was noted in male and female rats exposed at 6 mg/m³. Concentration-related histopathologic changes included focal erosion with regenerative hyperplasia and squamous metaplasia of the respiratory epithelium. Acute inflammation and hyperplasia of the respiratory epithelium were also found.

One group of 56 male rats was exposed to a mean CS concentration of 1,470 or 1,770 mg/m³ for 5 min/day for 5 days and another group of 49 male rats was exposed at a mean concentration of 12.5 or 14.8 mg/m³ for 80 min/day for 9 days to (Ballantyne and Callaway 1972). Exposures to the thermally-generated CS aerosol (MMD of 1-2 micrometers) were conducted in a 1-m³ chamber, with chamber air sampled continuously throughout exposure at a rate of 1 L/min using a double cone filter. The samples were analyzed for CS content (details not provided). Groups of three to five survivors were killed after 1, 6, and 24 h and 2, 3, 4, 5, 7, 10, 14, and 21 days, and gross and microscopic examinations were performed. All animals survived the 5-min exposures. Histopathologic examination revealed minimal congestion of the alveolar capillaries after 1 or 6 h in two of five rats and a few scattered alveolar hemorrhages after 2 days in one of four rats.

Scattered patches of bronchopneumonia were found in one of five rats after 7 days, in one of three rats after 8 days, one of three rats after 10 days, and two of five rats after 18 days. Pathologic changes in control rats included scattered alveolar hemorrhages in two of 11 rats and subacute mucoid enteritis in one of 11 rats. Death occurred in five of the 49 rats exposed at 12.5 or 14.8 mg/m³ for 80 min/day; one died after the seventh exposure, two after the eighth exposure, and two died 5 days after the final exposure. Necropsy revealed widespread acute bronchopneumonia. Histopathologic examination of the surviving animals revealed lesions for up to 5 days after exposure and not thereafter.

3.3.2. Mice

Groups of five male and five female B6C³F1 mice were exposed to CS₂ at concentrations of 0, 1, 3, 10, 30, or 100 mg/m³ for 6 h/day, 5 days/week for 2 weeks (NTP 1990). All mice exposed at 10 mg/m³ and greater died before study termination. Mice from all exposure groups exhibited adverse clinical signs, ranging from erythema and blepharospasm at the lower concentrations to dacryorrhea, mouth breathing, listlessness, and mouth breathing at the higher concentrations. Mice exposed at 1 mg/m³ gained more weight over the exposure period than controls, but generally lost body weight at exposure concentrations of 3 mg/m³ and higher.

Groups of 10 male and 10 female B6C³F1 mice were exposed to CS₂ at 0, 0.4, 0.75, 1.5, 3, or 6 mg/m³ for 6 h/day, 5 days/week for 13 weeks (NTP 1990). All mice exposed at 6 mg/m³ died and one male and one female mouse from the 3-mg/m³ group died during the second week of exposure. Closed or partially-closed eyes during exposure were observed in mice from all exposure groups through week 6, and in mice exposed at 3 mg/m³ during weeks 12 and 13. Concentration-related decreases in body weight compared with controls were found in all exposure groups; final mean body weights of mice in the 3-mg/m³ group were 13% lower for males and 9% lower for females. Exposure-related histopathologic changes were observed in mice exposed at 1.5 mg/m³ and higher, and included focal inflammation and squamous metaplasia (primarily in the nasal turbinates) and inflammation of the vomeronasal organ.

3.3.3. Rats, Mice, Guinea Pigs, and Rabbits

Groups of five to 10 guinea pigs, five rabbits, 10 rats, and 10-20 mice were exposed to CS at approximate concentrations of 30-40 mg/m³ for 5 h/day for 1-7 successive days (Ballantyne and Callaway 1972). An anti-riot grenade containing 0.5 to 0.75 g of CS was ignited every 30 min in a 10-m³ static chamber to maintain the nominal concentration. The investigators stated that concentrations were determined by continuous sampling throughout the exposure, but no details were provided. Animals were removed to fresh air following each exposure, and were maintained for a 14-day post-exposure period. All animals that died and the survivors killed at the end of the study were given gross and histologic examinations. A summary of the mortality data is presented in Table 7-12. The description of clinical signs was limited to a statement that

rabbits and rats exhibited more rhinorrhea and lacrimation than did mice, whereas guinea pigs showed few clinical signs apart from occasional sneezing during the first hour of exposure. Necropsy of animals that died revealed moderate-to-marked congestion of the alveolar capillaries and intrapulmonary veins and inter- and intra-alveolar areas of hemorrhage; many of the animals that died also had congestion of the liver, kidneys, and small intestine. Moderate pulmonary edema was noted in a “few of the animals.” No residual pathologic changes were found in animals that survived until the end of the study.

Species	Exposure	No. Days	Concentration (mg/m ³)	Mortality (%)	Abd/No. in
Guinea Pig	5	1	100	0	0/10
		2	100	25	2/8
		3	100	50	5/10
		4	100	75	7/10
Rabbit	5	1	100	0	0/10
		2	100	10	1/10
		3	100	20	2/10
Rat	5	1	100	0	0/10
		2	100	10	1/10
		3	100	20	2/10

TABLE 7-12

Summary of Mortality Data in Different Species Exposed to Tear Gas for 5 Hours per Day for Up to 7 Days.

3.4. Developmental and Reproductive Toxicity

Groups of 22-24 pregnant Porton strain rats or 12 pregnant New Zealand white rabbits were exposed to CS aerosol for 5 min/day on gestation days 6-15 or 6-18, respectively (Upshall 1973). CS The aerosol had a particle size of 1-2 micrometers and was generated by melting pure crystalline CS at 120°C using a Collison spray. A preliminary study investigated exposure to CS at 0 or 20 mg/m³, and was followed by a concentration-response study that evaluated CS at concentrations of 0, 6, 20, or 60 mg/m³. Control rats were recaged and moved out of their normal environment during the test-group exposure, and control rabbits were exposed to a siliconized silica aerosol at 60 mg/m³. Additional control groups of pregnant rats were exposed to a particulate aerosol (60 mg/m³ of Neosil) or to water aerosol to evaluate the stress of aerosol exposure. Rats were killed on gestation day 21 and rabbits on gestation day 30. Cesarean sections were performed, and the fetuses were evaluated for skeletal or visceral abnormalities. In addition, the lungs, liver, kidneys, and adrenal glands from the rabbit dams in the concentration-response study were evaluated histologically. No definitive effects of treatment were noted. In the preliminary rat study, exposed animals exhibited a decrease in maternal weight gain compared with controls (-23%), but a clear concentration-response relationship was not observed in the main study (-23, -12, and 15% for the 6, 20, or 60 mg/m³ groups, respectively). Fetal weight appeared to decrease with increasing concentration in the main rat study (3.3, 3.2, and 3.1 g, respectively, vs. 3.5 for controls), but the fetal weights were comparable those in other studies. No other statistically significant effects were observed. No exposure-related effects were found in exposed rabbits or their offspring. Although the exposure concentrations were sufficient to cause extreme irritation, clinical signs in exposed rats and rabbits were not reported.

3.5. Genotoxicity

In general, CS was not mutagenic to *Salmonella typhimurium*. Mutations were not induced with or without the presence of S9 at CS concentrations of 12.5-800 µg/plate in strains TA97a, TA98,

TA100, TA102, or TA104 (Meshram et al. 1992); of up to 1.5 mg/plate in strains TA98, TA100, TA1535, or TA1537 (Wild et al. 1983); ranging from 10 µg/plate to 2 mg/plate in strains TA98, TA1535, TA1537, or TA1538 (von Däniken et al. 1981); or at CS₂ concentrations of 3.3-333 µg/plate in strains TA98, TA100, TA1535, or TA1537 (NTP 1990). Equivocal responses for CS and CS₂ were reported in strain TA100 only without S9 (von Däniken et al. 1981; NTP 1990), and for CS₂ in strain TA97 but only with 30% S9 (NTP 1990). Cytotoxicity from CS was observed starting at 200 µg/plate, but the presence of 30% S9 generally reduced the cytotoxicity.

Other in vitro genotoxicity testing was generally positive. CS induced sister chromatid exchanges and chromosomal aberrations in Chinese hamster ovary cells both with and without S9 at CS₂ concentrations of 6 µg/mL and greater (NTP 1990). Trifluorothymidine resistance in mouse L5178Y lymphoma cells was induced in the absence of S9 at a CS concentration of 2.5 µg/mL (McGregor et al. 1988; NTP 1990). V79 Chinese hamster cells exposed to CS in culture at 19, 38, or 75 µM for 3 h and evaluated 6 days later showed reduced survival (by about 20, 30, and 80%, respectively; estimated from a graph), and exhibited a concentration-related increase in the frequency of mutants resistant to 6-thioguanine (mutations induced approximately 4- to 5-fold above controls at the highest concentration) (Ziegler-Skylakakis et al. 1989). Exposure to CS also increased the frequency of micronuclei by approximately 2-fold at 19 µM and up to 18-fold at 75 µM (measured 24 h after exposure), but did not induce DNA repair synthesis as assessed using the BrdUrd density-shift method. A concentration-dependent increase was observed in spindle cell disturbances, particularly C-metaphases (chromosomes completely scattered in cytoplasm and often highly contracted), when cells were exposed to CS at 5, 9, 19, or 38 µM for 3 h (Schmid and Bauchinger 1991). The C-mitotic effect was also reflected in the appearance of a metaphase block and the disappearance of other mitotic figures (prophases and ana-telophases). When a differential staining technique was applied to allow for visualization of the spindle apparatus and chromosomes, a concentration-dependent increase in the number of mitoses with abnormal spindles was again observed, particularly apolar mitoses (mitotic figures without any signs of polar spindle configurations) (Salassidis et al. 1991). Further investigation into the mechanism of CS-induced c-mitotic spindle damage found that exposure of cells to CS at 38 µM for 20 h or 3 h followed by 20 h of recovery resulted in an increase in the number of aneuploid cells and in the polyploid index (Schmid and Bauchinger 1991). The number of aneuploid cells and the polyploid index were increased to a much greater extent by exposure to the metabolite *o*-chlorobenzaldehyde than to CS, suggesting that this metabolite may play a role in the induction of spindle damage. A comparison of the effectiveness of various exposure conditions revealed that cells exposed to CS at concentrations of up to 38 µM for 20 h exhibited a concentration-dependent increase in the number of S-cells and the frequency of chromatid-type aberrations (single breaks, isolocus breaks and exchanges, and gaps). Exposure to CS for 3 h followed by a 20-h recovery period resulted in similar effects but was not as effective. No effects were observed when cells were incubated with the supernatant from the 3 h exposure (Bauchinger and Schmid 1992). The cell cycle time of the V79 cell line is approximately 8-10 h;

therefore, the cells had time to run through one or two S-phases.

Genotoxicity testing in vivo was generally negative. CS did not bind to DNA in the liver or kidneys of rats injected intraperitoneally with radiolabeled CS at 13 mg/kg and evaluated 8 or 75 h after dosing, but did bind to nuclear proteins in these organs (von Däniken et al. 1981). CS did not cause an increase in sex-linked recessive mutations in germ cells of male *Drosophila* when administered in the feed at concentrations ranging from 5×10^{-4} M to 2.6×10^{-3} M for 3 days (Wild et al. 1983), and did not increase micronucleated polychromatic erythrocytes in the bone marrow of NMRI mice administered CS by intraperitoneal injection at 19 or 38 mg/kg or by oral administration at 113 or 226 mg/kg (Wild et al. 1983). The oral dose of 226 mg/kg killed 10 of 13 exposed mice.

3.6. Chronic Toxicity and Carcinogenicity

Groups of 50 male and 50 female B6C³F1 mice and 50 male and 50 female F344/N rats were exposed to CS₂ at target concentrations of 0, 0.75, or 1.5 mg/m³ (mice) or 0, 0.075, 0.25, or 0.75 mg/m³ (rats) for 6 h/day, 5 days/week for 10⁵ weeks (NTP 1990). Rats exposed at 0.75 mg/m³ developed histopathologic changes in the respiratory and olfactory epithelium of the nasal passage and inflammation and proliferation of the periosteum of the turbinate bones. No neoplastic effects were present. Lesions seen in the nasal cavity of exposed mice included inflammation in the anterior middle portions of the nasal passage and focal hyperplasia and/or squamous metaplasia of the respiratory epithelium. No other adverse effects were noted. Female mice exhibited a statistically significant, exposure-related reduction in the incidences of hyperplasia and adenomas of the pituitary gland pars distalis (adenoma rates in the 0-, 0.75-, and 1.5-mg/m³ groups were 16/47, 5/46, and 1/46, respectively). Lymphomas in female mice also occurred with a significant negative trend (21/50, 12/50, and 8/50, respectively).

Groups of 75 male SPF Porton strain mice, 50 male Porton Wistar-derived rats, and 50 Dunkin Hartley guinea pigs were exposed to CS at nominal concentrations of 0, 3, 30, or 300 mg/m³ (MMD of 3-4 micrometers) for 1 h/day, 5 days/week for up to 55 exposures (11 weeks) in mice and up to 120 exposures (24 weeks) in rats and guinea pigs (Marrs et al. 1983b). Exposure at the high concentration resulted in excessive mortality in mice and guinea pigs within days of exposure; therefore, tests at the high concentration was discontinued after three exposures in mice and after five exposures in rats and guinea pigs (the number of deaths were not provided) (Marrs et al. 1983b). During the first month of the experiment, 17% of the mice and 46% of the guinea pigs in the high-concentration groups died. A significant trend ($p < 0.001$) was found in the incidence of early death in mice with concentration. The investigators also reported a significant trend ($p < 0.001$) in the incidence of early death with concentration in guinea pigs; however, most of the mortality in guinea pigs occurred during the first month. Post-mortem examination of 10 guinea pigs that died during exposure revealed acute alveolitis in seven of the animals, with mild alveolitis present in the other three. The cause of death in mice that died

during exposure to CS could not be determined. The investigators reported that toxic signs were not usually observed, and that death occurred suddenly and without warning. No cause of death could be ascribed to animals that died during the observation period. CS exposure did not affect the growth of rats or guinea pigs, but did result in a concentration-related decrease in the growth of mice. No definitive, exposure-related histologic findings were observed in mice, rats, or guinea pigs at the end of the study. No exposure-related neoplasms were found.

3.7. Summary

Clinical signs in the acute and repeated-dose animal studies suggest that CS is highly irritating. The majority of the acute inhalation exposure data in animals focused primarily on lethality, and death was generally caused by pulmonary edema and congestion. Renal damage was also occasionally noted, but may have been secondary to anoxia. Results of genotoxicity tests were mixed. Results in gene mutations tests using *S. typhimurium* were generally negative, as were results of in vivo genotoxicity assays. CS induced trifluorothymidine resistance in mouse L5178/TK lymphoma cells in the absence of S9, and induced both sister chromatid exchanges and chromosomal aberrations in Chinese hamster ovary cells in the presence and absence of S9. No developmental toxicity was found in rats or rabbits, and there was no evidence of carcinogenicity in rats or mice.

4. SPECIAL CONSIDERATIONS

4.1. Metabolism and Disposition

4.1.1. Absorption

One cat with a cannulated trachea was exposed to CS aerosol by an oral-nasal mask to assess absorption of CS by the upper respiratory tract (cannulation prevented access to the lower respiratory tract), while a second cat was exposed via a tracheal tube to assess absorption by the lower respiratory tract (Leadbeater 1973). Blood concentrations of CS and its metabolites after exposure to the upper and lower respiratory tract were about 30 and 80%, respectively, of those measured in intact cats.

4.1.2. Toxicokinetics

The half-lives of CS, 2-chlorobenzylmalonitrile, and 2-chlorobenzaldehyde were measured in cats and rabbits (Leadbeater 1973; Paradowski 1979). The chemicals were administered directly into the femoral artery via a cannula in cats and directly into the ear vein of rabbits. The half-lives of CS, 2-chlorobenzylmalonitrile, and 2-chlorobenzaldehyde in cats were 5.5, 9.5, and 4.5 sec, respectively, and in rabbits they ranged from 19-25, 38-55, and 38-41 sec, respectively. The in vitro half-lives of these chemicals in the blood of cats, humans and rats were also measured. In cat blood, the half-life was 5 sec for CS, 470 sec for 2-chlorobenzylmalonitrile, and 70 sec for

2-chlorobenzaldehyde. The respective half lives in humans were 5, 660, and 15 sec and in rats were 7, 30, and 15 sec (Leadbeater 1973). The in vitro half-life of CS in the blood of rabbits was approximately 60 sec; the investigators postulated that this half-life might be longer than those of rats, cats, and humans because of the higher concentration of CS tested in rabbits (Paradowski 1979).

CS incubated with rat liver homogenate for 5 min (ethanol-buffer; pH 7.4; 37°C) resulted in a 59% decrease in the initial amount of glutathione, with 26% of the depletion occurring spontaneously (non-enzymatically) (Rietveld et al. 1986). Binding to glutathione in vivo was confirmed by enhanced urinary thioether excretion in rats following intraperitoneal administration of CS (Rietveld et al. 1983, 1986). The thioether was identified as 2-chlorobenzylmercapturic acid.

4.1.3. Metabolism

Metabolism of CS appears to be qualitatively similar in different species. In vivo, CS can be hydrolyzed to 2-chlorobenzaldehyde or malononitrile or can be reduced to 2-chlorobenzyl malononitrile (see Figure 7-1) (Leadbeater 1973; Paradowski 1979). 2-Chlorobenzaldehyde can then be either oxidized to 2-chlorobenzoic acid for subsequent glycine conjugation or reduced to 2-chlorobenzyl alcohol for ultimate excretion as 2-chlorobenzyl acetyl cysteine or 2-chlorobenzyl glucuronic acid. Malononitrile can break down to cyanide, and be excreted as thiocyanate. The reduction of CS to 2-chlorobenzyl malononitrile is a relatively minor pathway; 2-chlorobenzyl malononitrile can be conjugated with glycine or can be hydrolyzed to 2-chlorophenyl 2-cyanopropionate.

FIGURE 7-1

Predominant metabolic pathways of tear gas in rats proposed by Leadbeater (1973), Paradowsk (1979), and Rietveld et al. (1983).

Radiolabeled CS was administered intravenously to rats at 0.08, 0.8, and 80 $\mu\text{mol/kg}$ (3H-ring labeled), 0.8 and 80 $\mu\text{mol/kg}$ (^{14}C -cyanide labeled), or 0.8 and 80 $\mu\text{mol/kg}$ of ($^{14}\text{C}=\text{C}$ side-chain labeled) (Brewster et al. 1987). Rats were also treated intragastrically with CS at 80, 106, and 159 $\mu\text{mol/kg}$ (^{14}C -cyanide labeled). The major urinary metabolites recovered in rats up to 96 h after intravenous or intragastric administration of CS were 2-chlorohippuric acid (49% of dose), 2-chlorobenzyl glucuronic acid (10%), 2-chlorobenzyl cysteine (8%), and 2-chlorobenzoic acid (8%), and minor metabolites included 2-chlorophenyl acetyl glycine (3%), 2-chlorobenzyl alcohol (1.6%), and 2-chlorophenyl 2-cyano propionate (1.6) (see Figure 7-1).

In another investigation, urinary concentrations of cyanide and thiocyanate were measured over a 24-h period in untreated rats, in rats administered CS intravenously, or in rats exposed to the CS

hydrolysis product malononitrile intraperitoneally or intragastrically (Brewster et al. 1987). Following CS and malononitrile administration, urinary cyanide concentrations remained at or below baseline levels, while thiocyanate concentrations generally increased with the CS or malononitrile dose. The percentage molar conversion from CS to thiocyanate was 21.5% at an intraperitoneal dose of 212 $\mu\text{mol/kg}$ and 30% at an intragastric dose of 212 $\mu\text{mol/kg}$. In tests with malononitrile, the percentage was 60% or more at an intraperitoneal dose of 80 $\mu\text{mol/kg}$ or intragastric dose of 212 $\mu\text{mol/kg}$.

Metabolism in rabbits is similar to that in rats. The predominant biotransformation pathway in the blood of rabbits administered high doses of CS by intravenous injection (0.5 LD_{50} to the LD_{50}) was hydrolysis of CS to 2-chlorobenzaldehyde and malononitrile (~30-40%) (Paradowski 1979). A minor pathway involved reduction to 2-chlorobenzyl malononitrile (10%). The investigators indicated that the remaining 50-60% of the administered CS disappeared from the blood by other means; no other explanation was provided. The liver is involved in the metabolism of CS, as demonstrated by an increase in the half-lives of CS and its metabolites in the blood of rabbits when the liver was excluded from the circulation. More of the CS was accounted for after dosing, with approximately 75% of the CS hydrolyzed to 2-chlorobenzaldehyde and 15% reduced to 2-chlorobenzyl malononitrile. When the kidneys were excluded from the circulation, no changes were observed in CS or metabolites in the blood.

Maximum blood concentrations of CS and its derivatives in cats were attained 30 min after intragastric administration at 40 mg/kg (Leadbeater 1973). After 90 min, blood concentrations of 2-chlorobenzylmalonitrile and 2-chlorobenzaldehyde were still elevated, but CS concentrations had returned to zero. When anesthetized cats were exposed for 60 min via oral-nasal masks to CS aerosol (75 or 750 mg/m^3 of pyrotechnically-generated CS aerosol, 750 mg/m^3 of pure CS aerosol from molten CS, or 62.5 mg/m^3 of CS aerosol generated from an aqueous suspension of micronized CS in acetic acid using a Collison sprayer), concentrations of CS and 2-chlorobenzylmalonitrile rapidly reached steady values, but concentrations of 2-chlorobenzaldehyde continued to increase. Comparison of the blood concentrations resulting from exposure to CS at 750 and 75 mg/m^3 showed that there was not a 10-fold decrease in the concentration of CS and its metabolites 2-chlorobenzylmalonitrile and 2-chlorobenzaldehyde; the concentrations were reduced by 4.5, 7.7, and 5.9, respectively. Exposure of cats to CS at 100 mg/m^3 for 5 min/day for 4 days, followed by exposure to CS at 75 or 750 mg/m^3 , resulted in reduced blood concentrations of CS and its derivatives.

Rats receiving a single oral dose of CS at 50-500 mg/kg had lower blood concentrations of CS and its derivatives than cats (Leadbeater 1973). CS was only detected in high-dose group. Blood concentrations of 2-chlorobenzylmalonitrile and 2-chlorobenzaldehyde in rats and cats did not increase in a dose-related manner. Rats exposed by inhalation to CS aerosol at concentrations of 14-245 mg/m^3 for 5 min had measurable amounts of CS and 2-chlorobenzylmalonitrile in their blood immediately after exposure, but 2-chlorobenzaldehyde was detected only in rats exposed

at concentrations greater than 100 mg/m³.

Animal data suggest that CS should be absorbed by the human respiratory tract following inhalation exposure, and that metabolism of CS should proceed via a pathway similar to those found in laboratory animals. However, humans are not able to tolerate concentrations of CS as great as those tolerated by animals. Six healthy human males were exposed by inhalation to CS at 0.5-1.5 mg/m³ over 90 min, and blood was drawn before and after exposure to measure CS and its derivatives (Leadbeater 1973). Two men left the chamber within 20 min. CS and 2-chlorobenzaldehyde were not detected in the blood of any of the volunteers, and only a trace of 2-chlorobenzylmalonitrile was detected in the blood of one man who remained in the chamber for the entire exposure.

4.1.4. Distribution and Elimination

To evaluate the fate of CS, radiolabeled CS was administered intravenously (3H-ring labeled, ¹⁴C-cyanide labeled, or ¹⁴C=C side-chain labeled) or intragastrically (¹⁴C-cyanide labeled) to rats, and urine, feces, and CO₂ were collected for 96 h (Brewster et al. 1987). The majority of the administered dose was recovered in the urine (44.4 to 100%). Recovery in feces was 1.2-23.4%, and recovery in CO₂ was minimal at 0-2.1%. Comparison of recovery data for the three different radiolabels after intravenous administration showed that more radioactivity was recovered in the feces of rats administered the ¹⁴C=C sidechain labeled CS (21-23%) than from rats administered the other two labels (4-8%).

Male mice were administered ¹⁴CN-CS by intravenous injection, and were killed at selected intervals to evaluate distribution by autoradiography (Brewster et al. 1987). A significant amount of radioactivity was present in the gastrointestinal tract after 5 min. After 1 h, significant amounts of radioactivity were present in the gastrointestinal tract, urinary bladder, mouth, and esophagus, with lesser amounts in the blood, liver, and salivary glands. At 24 h, most of the residual radioactivity was present in the mouth, salivary glands, gastrointestinal tract, or urinary bladder.

4.2. Mechanism of Toxicity

CS is an SN₂ alkylating agent and, therefore, reacts directly with nucleophilic compounds (Cucinell et al. 1971). Consequently, sulfhydryl-containing enzymes and other biologic compounds are prime targets. Most notably, CS reacts rapidly with the disulfhydryl form of lipoic acid, a coenzyme in the pyruvate decarboxylase pathway. In in vitro studies, CS reacted readily with cysteine, N-acetyl L-cysteine, glutathione, dithiothreitol, and lipoic acid, and had first-order reaction constants of 0.33, 0.42, 0.85, 4.88, and 10.4, respectively. Incubation of rat liver homogenate with CS for 5 min (ethanol-buffer; pH 7.4; 37°C) resulted in a 59% decrease in the initial amount of glutathione, with 26% of the depletion occurring spontaneously (non-enzymatically) (Rietveld et al. 1986). Binding to glutathione in vivo was confirmed by enhanced

urinary thioether excretion in rats after intraperitoneal administration of CS; the thioether was identified as 2-chlorobenzylmercapturic acid (Rietveld et al. 1983, 1986). In another study, rats administered CS intraperitoneally at a dose that was 120% of the LD₅₀ became moribund approximately 30 min after injection (most likely due to the relatively slow generation of cyanide from the malononitrile metabolite). The role of cyanide in CS-induced lethality is supported by the observation that administration of thiosulfate intravenously reduced mortality by 65% compared with control rats (21/32 exposed rats survived vs. 1/11 control rats). Intravenous administration of CS at 8 mg/kg in dogs resulted in a rapid drop in the plasma sulfhydryl concentration, which returned to normal within approximately 3 h (Cucinell et al. 1971).

4.3. Other Relevant Information

4.3.1. Species Variability

CS is a potent acute irritant. Ocular and pulmonary toxicity results from direct contact with CS and its associated alkylating properties; therefore, the mechanism of action is not expected to vary greatly between species. Ballantyne and Swantson (1978) calculated LCT50 values of 88,480 mg-min/m³ for rats, 67,200 mg-min/m³ for guinea pigs, 54,090 mg-min/m³ for rabbits, and 50,010 mg-min/m³ for mice. These values are well within a factor of two of each other.

4.3.2. Susceptible Populations

CS is an irritant and the mechanism of toxicity is a direct contact effect; therefore, the mechanism of action is not expected to vary greatly between individuals. The reactions in people with jaundice, hepatitis, or peptic ulcer or those that were 50-60 years old were similar to those of “normal” volunteers when exposed at highly irritating concentration of CS for short durations (Gutentag et al. 1960; Punte et al. 1963). Subjects with a history of drug allergies or sensitivities, hay fever, or asthma also tolerated exposure to CS and were similar to normal subjects, but the group with pre-existing conditions had a higher percentage of individuals with more severe chest symptoms (many of them laying prostrate on the ground for several minutes). However, no wheezing or rhonchi were heard, and recovery was as rapid as that seen in other exposure groups.

4.3.3. Concentration-Exposure Duration Relationship

The concentration-exposure time relationship for many irritant and systemically-acting vapors and gases can be described by the equation $C^n \times t = k$, where the exponent n ranges from 0.8 to 3.5 (ten Berge et al. 1986). The value of n for CS was determined on the basis of acute lethality data from studies of rats, mice, rabbits, guinea pigs, dogs, and monkeys (see Table 7-13). The dose-response software of ten Berge (2006) was used in the analyses (see Appendix A for details).

TABLE 7-13 Values of the Exponent n for Tear Gas

Species	n value	95% Confidence Limits
Rat	0.704	0.543-0.865
Mouse	0.701	0.509-0.892
Rabbit	0.658	0.407-0.949
Chinese pig	0.559	0.018-1.099
Dog	0.350	-1.404-0.751
Monkey	0.187	-0.281-0.656

TABLE 7-13

Values of the Exponent n for Tear Gas.

5. DATA ANALYSIS FOR AEGL-1

5.1. Human Data Relevant to AEGL-1

Several studies describe irritation in humans cause by CS (see [Table 7-7](#)); however, the severity of the effects exceeds those defined by AEGL-1.

5.2. Animal Data Relevant to AEGL-1

No animal studies of CS were available for deriving AEGL-1 values.

5.3. Derivation of AEGL-1 Values

AEGL-1 values are not recommended because no studies were available in which toxicity was limited to AEGL-1 effects. Effects observed at the lowest tested concentrations exceeded the severity of those defined by AEGL-1. Absence of AEGL-1 values does not imply that exposure below the AEGL-2 values are without adverse effects.

6. DATA ANALYSIS FOR AEGL-2

6.1. Human Data Relevant to AEGL-2

Five subjects exposed to CS at 0.71-0.78 mg/m³ (average concentration 0.75 mg/m³, calculated from the six interval measurements) tolerated a 60 min exposure ([Beswick et al. 1972](#)). All subjects reported ocular stinging and watering, increased salivation, cough, and face stinging. Other effects reported by some of the subjects included throat irritation (4 subjects), nasal stinging and running (3 subjects), mouth stinging (2 subjects), chest burning (2 subjects), nausea (2 subjects), and headache (2 subjects). Nausea was likely due to swallowing large amounts of saliva and the headaches were likely due to frontal sinus irritation ([Beswick et al. 1972](#)). In another study, four subjects exposed to CS at 1.5 mg/m³ tolerated a 90 min exposure, but experienced clinical signs of irritation. One subject developed nasal irritation within 2 min, three subjects developed headache (at 45, 50, and 83 min), and all four experienced ocular irritation (at 20, 24, 70, and 75 min) ([Punte et al. 1963](#)). When the CS concentration was gradually increased over the course of 60 min, most of the 30 subjects were able to tolerate exposure to concentrations ranging from 0.31 to 2.3 mg/m³; one subject left at 5 min because of vomiting but returned for the duration of the exposure, another vomited at 55 min of exposure, and one subject left after 8 min because of irritation ([Beswick et al. 1972](#)). The two cases of vomiting were attributed to swallowing large amounts or saliva. Clinical signs noted during the 60 min exposure

included ocular, nasal, mouth, and throat irritation, nausea, chest discomfort, headache, and stinging of the face.

6.2. Animal Data Relevant to AEGL-2

Blinking, mild pulmonary congestion, and emphysema were observed in monkeys exposed to CS at 900 mg/m³ for 3 min or 1,700 mg/m³ for 5 min. Monkeys exposed at 2,500 mg/m³ for 32 min exhibited blinking, labored respiration, coughing, oral and nasal discharge, vomiting, decreased activity, pulmonary edema, and congestion (Striker et al. 1967). Mice exposed to CS at 40 mg/m³ for 5 h had rhinorrhea and lacrimation, and guinea pigs exposed at 45 mg/m³ for 5 h showed occasional sneezing during the first hour of exposure.

6.3. Derivation of AEGL-2 Value

AEGL-2 values are based on human exposure to CS at 0.75 mg/m³ for 60 min (Beswick et al. 1972). All five subjects tolerated the exposure, but experienced ocular irritation, increased salivation, and coughing; some subjects also reported nasal, mouth, and throat irritation, nausea, and headache. An intraspecies uncertainty factor of 3 was applied because contact irritation is a portal-of-entry effect and is not expected to vary widely among individuals. This factor is also supported by the finding that responses of volunteers with jaundice, hepatitis, or peptic ulcer or who were 50-60 years old were similar to those of “normal” volunteers when exposed at a highly irritating concentration of CS for short durations. The ability to tolerate CS at 14-73 mg/m³ and the recovery time in volunteers with a history of drug allergies, seasonal allergies, asthma, or drug sensitivity were similar to “normal” volunteers; although more severe chest symptoms were reported in the volunteers with pre-existing conditions (Gutentag et al. 1960; Punte et al. 1963). An interspecies uncertainty factor of 1 was applied because the study was conducted in humans. A modifying factor of 3 was also used because the effects observed at 0.75 mg/m³ were considered AEGL-2 effects (watering eyes could impair escape). Time scaling was not performed because ocular irritation is a function of direct contact with the CS and is unlikely to increase with duration of exposure at this level of severity (NRC 2001). AEGL-2 values for CS are presented in Table 7-14, and the calculations are in Appendix B.

10 min	30 min	1 h	4 h	8 h
0.083 mg/m ³				

TABLE 7-14

AEGL-2 Values for Tear Gas.

These values are supported by the Punte et al. (1963) study in which four subjects tolerated a 90-min exposure at 1.5 mg/m³ and reported ocular and nasal irritation and headache. The values are also supported by other experiments conducted by Beswick et al. (1972). When an additional 30 subjects were exposed for 60 min to CS at 0.31-2.3 mg/m³, one subject left at 5 min because of vomiting, but returned for the duration of the exposure, and another vomited at 55 min of

exposure. Both cases of vomiting were attributed to swallowing large amounts of saliva. One subject voluntarily left after 8 min because of irritation; this subject was exposed at 0.56-0.86 mg/m³ (AEGL-2 values are below this range).

7. DATA ANALYSIS FOR AEGL-3

7.1. Human Data Relevant to AEGL-3

No human studies of CS were available for deriving AEGL-3 values.

7.2. Animal Data Relevant to AEGL-3

Animal lethality data are available for rats, mice, rabbits, guinea pigs, dogs, and monkeys exposed to varying concentrations of CS for varying durations (McNamara et al. 1969; Ballantyne and Callaway 1972; Ballantyne and Swanston 1978). Exposure durations ranged from 5 to 300 min and concentrations of CS ranged from 37 to 5,176 mg/m³. Mortality incidences ranged from 0 to 100%, depending on concentration-duration pairings. The experimental parameters are summarized in Tables 7-8, 7-10, 7-11, and 7-12.

7.3. Derivation of AEGL-3 Values

Using the rat, mouse, rabbit, guinea pig, dog, and monkey data sets of McNamara et al. (1969), Ballantyne and Callaway (1972), and Ballantyne and Swanston (1978), the lethality threshold for CS at each AEGL-3 exposure duration was calculated using the probit analysis-based dose-response program of ten Berge (2006) (see Appendix A). The threshold for lethality was set at the LC₀₁. The rat, mouse, and rabbit data all yielded similar time-scaling values and AEGL-3 values (see Appendix A). Large variances in the dog and monkey data precluded calculation of 95% confidence intervals. The rat data set was used to derive AEGL-3 values, because it yielded values that were the most consistent with the available human data. Time scaling was performed using the equation $C^n \times t = k$, where the exponent n ranges from 0.8 to 3.5 (ten Berge et al. 1986). An empirical value for n of 0.70 was determined on the basis of the rat data. The 4-h AEGL-3 value was adopted as the 8-h AEGL-3 value because time scaling yielded an 8-h value inconsistent with the AEGL-2 values, which were derived from a rather robust human dataset. A total uncertainty factor of 10 was applied. A factor of 3 was used to account for interspecies differences, because clinical signs are likely caused by a direct chemical effect on the tissues and this type of portal-of-entry effect is unlikely to vary greatly between species. Furthermore, calculated LC_{t50} values for different species are all well within a factor of 2 of each other (88,480 mg-min/m³ for rats, 67,200 mg-min/m³ for guinea pigs, 54,090 mg-min/m³ for rabbits, and 50,010 mg-min/m³ for mice) (Ballantyne and Swanston 1978). An uncertainty factor of 3 was used to account for intraindividual variability because contact irritation is a portal-of-entry effect and is not expected to vary widely among individuals. As noted above in support of the

AEGL-2 values, a factor of 3 is also supported by the results of studies by [Punte et al. \(1963\)](#) and [Gutentag et al. \(1960\)](#) in subjects with pre-existing conditions. AEGL-3 values for CS are presented in [Table 7-15](#), and calculations presented in [Appendix B](#).

Exposure Duration	10 min	30 min	1 h	4 h	8 h
AEGL-3	140 mg/m ³	29 mg/m ³	11 mg/m ³	1.5 mg/m ³	1.5 mg/m ³

TABLE 7-15

AEGL-3 Values for Tear Gas.

The AEGL-3 values are considered protective. No mortality was noted in rats, rabbits, or mice exposed to CS at 1,802, 1,434, or 4,250 mg/m³ for 10 min, respectively ([Ballantyne and Swanston 1978](#)), suggesting that the 10-min AEGL-3 of 140 mg/m³ is appropriate. Similarly, no deaths were observed in 10 mice or five guinea pigs exposed at 40 or 44.7 mg/m³, respectively, for 5 h ([Ballantyne and Callaway 1972](#)). One of 10 rats died after exposure to CS at 37 mg/m³ for 5 h ([Ballantyne and Callaway 1972](#)). These data support the 4-h AEGL-3 of 1.5 mg/m³.

8. SUMMARY OF AEGLs

8.1. AEGL Values and Toxicity End Points

AEGL-1 values were not recommended because effects exceeding the severity of AEGL-1 were detected at the lowest concentrations tested.

AEGL-2 values are based on irritation in humans and AEGL-3 values are based on an estimated threshold for lethality in rats. AEGL values for tear gas are presented in [Table 7-16](#).

Classification	10 min	30 min	1 h	4 h	8 h
AEGL-1 (Irritation)	140	29	11	1.5	1.5
AEGL-2 (Irritation)	140	29	11	1.5	1.5
AEGL-3 (Lethality)	140	29	11	1.5	1.5

TABLE 7-16

AEGL Values for Tear Gas.

8.2. Other Standards and Guidelines

Standards and guidelines for CS are presented in [Table 7-17](#). Differences between the emergency response planning guideline 3 (ERPG-3) and the 1-h AEGL-3 value and between the immediately dangerous to life or health and 30-min AEGL-2 values are due to differences in the point of departure and uncertainty factors. The ERPG-3 is based on a 1-h LC₅₀ of 1,000 mg/m³ and undisclosed uncertainty factors ([AIHA 2008](#)). The IDLH is based on a Department of Army safety guide, which reported that a 2-min exposure to CS at 2-10 mg/m³ was considered intolerable by six of 15 people ([NIOSH 1996](#)).

Guideline	10 min	30 min	1 h	4 h	8 h
AEGL-1	140	29	11	1.5	1.5
AEGL-2	140	29	11	1.5	1.5
AEGL-3	140	29	11	1.5	1.5
ERPG-1	140	29	11	1.5	1.5
ERPG-2	140	29	11	1.5	1.5
ERPG-3	1,000	1,000	1,000	1,000	1,000
IDLH	10	10	10	10	10

TABLE 7-17

Standards and Guidelines for Tear Gas.

8.3. Data Adequacy and Research Needs

Inadequate data are available to derive AEGL-1 values for CS. Adequate human data are available for deriving AEGL-2 values, and animal data are available for deriving AEGL-3 values. Additional data providing information at exposures that produce minimal irritation would be useful for deriving AEGL-1 values.

APPENDIX A. TIME-SCALING CALCULATIONS FOR TEAR GAS

The relationship between dose and time for any given chemical is a function of the physical and chemical properties of the substance and the unique toxicologic and pharmacologic properties of the individual substance. Historically, the relationship according to Haber (1924), commonly called Haber's Law or Haber's Rule ($C \times t = k$, where C = exposure concentration, t = exposure duration, and k = a constant), has been used to relate exposure concentration and duration to effect (Rinehart and Hatch 1964). This concept states that exposure concentration and exposure duration may be reciprocally adjusted to maintain a cumulative exposure constant (k) and that this cumulative exposure constant will always reflect a specific quantitative and qualitative response. This inverse relationship of concentration and time may be valid when the toxic response to a chemical is equally dependent on the concentration and the exposure duration. However, an assessment by ten Berge et al. (1986) of LC_{50} data for certain chemicals revealed chemical-specific relationships between exposure concentration and exposure duration that were often exponential. This relationship can be expressed by the equation $C^n \times t = k$, where n represents a chemical-specific (and even a toxic end point-specific) exponent. The relationship described by this equation is basically the form of a linear regression analysis of the log-log transformation of a plot of C vs. t . ten Berge et al. (1986) examined the airborne concentration (C) and short-term exposure duration (t) relationship relative to death for approximately 20 chemicals and found that the empirically derived value of n ranged from 0.8 to 3.5 among this group of chemicals. Hence, the value of the exponent n in the equation $C^n \times t = k$ quantifies the relationship between exposure concentration and exposure duration. Haber's Rule is the special case where $n = 1$. As the value of n increases, the plot of concentration vs. time yields a progressive decrease in the slope of the curve.

An n of 0.70 mg/m^3 for CS was obtained by analysis of lethality data in rats (McNamara et al. 1969; Ballantyne and Callaway 1972; Ballantyne and Swanston 1978) using the software of ten Berge (2006). This exposure-time relationship for lethality was considered appropriate for deriving AEGL-3 values. The 4-h AEGL-3 value was adopted as the 8-h AEGL-3 value because time scaling yielded an 8-h value inconsistent with the AEGL-2 values that were derived from robust human data.

TABLE A-1 Results of ten Berge Program (1% Lethality)

Species	Exponent n	LC_{01} Point Estimate, mg/m^3 (95% confidence limits)	Reference(s)
---------	--------------	--	--------------

		10 min	30 min	1 h	4 h	8 h

APPENDIX B. DERIVATION OF AEGL VALUES FOR TEAR GAS

Derivation of AEGL-1 Values

AEGL-1 values are not recommended for CS because the effects observed at the lowest tested concentrations exceeded the severity of AEGL-1 effects.

Derivation of AEGL-2 Values

Key study:	Beswick, F.W., P. Holland, and K.H. Kemp. 1972. Acute effects of exposure to orthochlorobenzilidene malononitrile (CS) and the development of tolerance. <i>Br. J. Ind. Med.</i> 29(3):298-306.
Toxicity end point:	Human exposure to CS at an average concentration of $0.75 \text{ mg}/\text{m}^3$ for 60 min. All five subjects tolerated the exposure but reported ocular stinging and watering, increased salivation, coughing, and face stinging. Some subjects also reported throat irritation (4 subjects), nasal stinging and running (3 subjects), mouth stinging (2 subjects), chest burning (2 subjects), nausea (2 subjects), and headache (2 subjects).
Time scaling:	None. Irritation is a function of direct contact with CS and is unlikely to increase with duration of exposure at this level of severity (NRC 2001).
Uncertainty factors:	1 for interspecies differences 3 for intraspecies variability; contact irritation is a portal-of-entry effect and is not expected to vary widely between individuals. Value of 3 is also supported by a study that showed that volunteers with a history of jaundice, hepatitis, or peptic ulcer or those that were 50-60 years old had responses similar to those of “normal” volunteers when exposed at a highly

	irritating concentration of CS for short durations. The ability to tolerate exposure to CS at 14-73 mg/m ³ and the recovery time in people with a history of drug allergies, seasonal allergies, asthma, or drug sensitivity was similar to normal volunteers; although more severe chest symptoms were reported in the people with pre-existing conditions (Gutentag et al. 1960; Punte et al. 1963).
Modifying factor:	3, because effects observed at 0.75 mg/m ³ were AEGL-2 effects.
Calculations:	0.75 mg/m ³ ÷ 9 = 0.083 mg/m ³ (applied to all AEGL durations)

Derivation of AEGL-3 Values

Key studies:	McNamara, B.P., E.J. Owens, J.T. Weimer, T.A. Ballard, and F.J. Vocci. 1969. Toxicology of Riot Control Chemicals CS, CN, and DM. Edgewood Arsenal Technical Report EATR-4309. US Department of the Army, Edgewood Arsenal Medical Research Laboratory, Edgewood Arsenal, MD. November 1969.
	Ballantyne, B., and S. Callaway. 1972. Inhalation toxicology and pathology of animals exposed to o chlorobenzylidene malononitrile. Med. Sci. Law 12(1):43-65.
	Ballantyne, B., and D.W. Swanston. 1978. The comparative acute mammalian toxicity of 1-chloroacetophenone (CN) and 2-chlorobenzylidene malononitrile (CS). Arch. Toxicol. 40(2):75-95.
Toxicity end point:	L ₀₁ for rats; calculated using probit analysis-based dose-response program of ten Berge (2006), see Appendix A.

Exponent n	LC ₀₁ Point Estimate, mg/m ³ (95% confidence limits)				
	10 min	30 min	1 h	4 h	8 h
0.704 (0.543-0.865)	1,385 (477–2,500)	290 (97–496)	109 (32–196)	15 (3.1–35)	5.6 (-0.93–15)

Time scaling:	$C^n \times t = k$; n = 0.70 (based on rat lethality data). No time scaling was performed for the 8-h AEGL value, because time scaling yielded a value that was inconsistent with the AEGL-2 values that were derived from robust human data.
Uncertainty factors:	3 for interspecies differences. Effects from CS are likely caused by a direct chemical effect on the tissues. This type of portal-of-entry effect is unlikely to vary greatly between species. Value is also supported by calculated LCT ₅₀ values of 88,480 mg min/m ³ for rats, 67,200 mg min/m ³ for guinea pigs, 54,090 mg

	min/m ³ for rabbits, and 50,010 mg min/m ³ for mice (Ballantyne and Swanston 1978); values all well within a factor of two of each other.
	3 for intraspecies variability. Effects from CS are likely caused by a direct chemical effect on the tissues. This type of portal-of-entry effect is not likely to vary greatly among individuals. Value is also supported by a study that showed that volunteers with a history of jaundice, hepatitis, or peptic ulcer or those that were 50-60 years old had responses similar to those of “normal” volunteers when exposed at a highly irritating concentration of CS for short durations. The ability to tolerate exposure to CS at 14-73 mg/m ³ and the recovery time in people with a history of drug allergies, seasonal allergies, asthma, or drug sensitivity was similar to normal volunteers; although more severe chest symptoms were reported in the people with pre-existing conditions (Gutentag et al. 1960; Punte et al. 1963).
Calculations:	
10-min AEGL-3:	$1,385 \text{ mg/m}^3 \div 10 = 140 \text{ mg/m}^3$
30-min AEGL-3:	$290 \text{ mg/m}^3 \div 10 = 29 \text{ mg/m}^3$
1-h AEGL-3:	$109 \text{ mg/m}^3 \div 10 = 11 \text{ mg/m}^3$
4-h AEGL-3:	$15 \text{ mg/m}^3 \div 10 = 1.5 \text{ mg/m}^3$
8-h AEGL-3:	Set equal to the 4-h AEGL-3 of 1.5 mg/m ³

APPENDIX C. ACUTE EXPOSURE GUIDELINE LEVELS FOR TEAR GAS

Derivation Summary

AEGL-1 VALUES

AEGL-1 values are not recommended for CS because the effects observed at the lowest tested concentrations exceeded the severity of AEGL-1 effects.

AEGL-2 VALUES

10 min	30 min	1 h	4 h	8 h
--------	--------	-----	-----	-----

10 min	30 min	1 h	4 h	8 h
0.083 mg/m ³	0.083mg/m ³	0.083 mg/m ³	0.083 mg/m ³	0.083 mg/m ³
Key reference: Beswick, F.W., P. Holland, and K.H. Kemp. 1972. Acute effects of exposure to orthochlorobenzilidene malononitrile (CS) and the development of tolerance. Br. J. Ind. Med. 29(3):298-306.				
Test species/Strain/Number: Humans, 5				
Exposure route/Concentration/Duration: Inhalation, 0.71-0.78 mg/m ³ (average: 0.75 mg/m ³) for 60 min				
Effects: Clinical signs of irritation. Ocular stinging and watering, increased salivation, cough, and face stinging was reported in all subjects. Additional signs of irritation included throat irritation (4 subjects), nasal stinging and running (3 subjects), mouth stinging (2 subjects), chest burning (2 subjects), nausea (2 subjects), and headache (2 subjects).				
End point/Concentration/Rationale: Ocular, nasal, mouth, and throat irritation, coughing, nausea, and headache at 0.75 mg/m ³ for 60 min.				
Uncertainty factors/Rationale:				
Total uncertainty factor: 3				
Interspecies: 1, because data were from human volunteers				
Intraspecies: 3, contact irritation is a portal-of-entry effect and is not expected to vary widely between individuals. Value is also supported by a study that showed that volunteers with a history of jaundice, hepatitis, or peptic ulcer and those that were 50-60 years old had responses similar to those of "normal" volunteers when exposed at a highly irritating concentration of CS for short durations. The ability to tolerate the exposure to CS at 14-73 mg/m ³ and the recovery time in people with a history of drug allergies, seasonal allergies, asthma, or drug sensitivity was similar to normal volunteers; although more severe chest symptoms were reported in the people with pre-existing conditions (Gutentag et al. 1960; Punte et al. 1963).				
Modifying factor: 3, because effects at 0.75 mg/m ³ were considered AEGL-2 effects.				
Animal-to-human dosimetric adjustment: Not applicable				
Time scaling: Not applied. Irritation is a function of direct contact with the CS and is unlikely to increase with duration of exposure at this level of severity (NRC 2001).				
Data adequacy: AEGL-2 values are supported by the data of Punte et al. (1963) and Beswick et al. (1972). Exposure of four subjects at 1.5 mg/m ³ for 90 min resulted in ocular and nasal irritation in all subjects and headache in 3 subjects (Punte et al. 1963). When a total of 30 subjects were exposed for 60 min to gradually increasing CS concentrations ranging from 0.31-2.3 mg/m ³ , one subject left at 5 min because of vomiting but returned for the duration of				

10 min	30 min	1 h	4 h	8 h
the exposure, and another vomited at 55 min of exposure (vomiting in both cases attributed to swallowing large amounts of saliva). One subject voluntarily left the exposure after 8 min because of irritation; this subject was exposed in the range of 0.56-0.86 mg/m ³ , and the AEGL-2 values are below this range.				

AEGL-3 VALUES

10 min	30 min	1 h	4 h	8 h	
140 mg/m ³	29 mg/m ³	11 mg/m ³	1.5 mg/m ³	1.5 mg/m ³

Test species/Strain/Number: Rat, various strains; 8, 10, 20, or 21 per group					
Exposure route/Concentration/Duration: Inhalation, 37-5,175 mg/m ³ for 5-300 min.					
Effects: Lethality					
End point/Concentration/Rationale: LC ₀₁ for rats calculated using probit-analysis dose-response program of ten Berge (2006).					
	LC ₀₁ Point Estimate, mg/m ³				
Exponent <i>n</i>	10 min	30 min	1 h	4 h	8 h
0.704 (0.543-0.865)	1,385 (477-2,500)	290 (97-496)	109 (32-196)	15 (3.1-35)	5.6 (-0.93-15)
Uncertainty factors/Rationale:					
Total uncertainty factor: 10					
Interspecies: 3, effects from CS are likely caused by a direct chemical effect on the tissues. This type of portal-of-entry effect is unlikely to vary greatly between species. Value is also					

10 min	30 min	1 h	4 h	8 h
supported by calculated LCT ₅₀ values of 88,480 mg min/m ³ for rats, 67,200 mg min/m ³ for guinea pigs, 54,090 mg min/m ³ for rabbits, and 50,010 mg min/m ³ for mice (Ballantyne and Swanston 1978); values are all well within a factor of two of each other.				
Intraspecies: 3, effects from CS are likely caused by a direct chemical effect on the tissues. This type of portal-of-entry effect is not likely to vary greatly among individuals. Value is also supported by a study that showed that volunteers with a history of jaundice, hepatitis, or peptic ulcer or those that were 50-60 years old had responses similar to those of “normal” volunteers when exposed at a highly irritating concentration of CS for short durations. The ability to tolerate the exposure to CS at 14-73 mg/m ³ and the recovery time in people with a history of drug allergies, seasonal allergies, asthma, or drug sensitivity was similar to normal volunteers; although more severe chest symptoms were reported in the people with pre-existing conditions (Gutentag et al. 1960; Punte et al. 1963).				
Modifying factor: None applied				
Animal-to-human dosimetric adjustment: Not applicable				
Time scaling: $C^n \times t = k$, where $n = 0.70$ based on rat lethality data. The 4-h AEGL-3 value was adopted as the 8-h AEGL-3 value because time scaling yielded an 8-h value inconsistent with the AEGL-2 values that were derived from robust human data.				
Data adequacy: The AEGL-3 values are considered protective. No mortality was noted in rats exposed to CS at 1,802 mg/m ³ for 10 min (Ballantyne and Swanston 1978), in rabbits at 1,434 mg/m ³ for 10 min (Ballantyne and Swanston 1978), or in mice and rabbits at 4,250 mg/m ³ for 10 min (Ballantyne and Callaway 1972). Dividing these concentrations by a total uncertainty factor of 10, yields values ranging from 140-425 mg/m ³ , suggesting that the 10-min AEGL-3 is appropriate. No mortality was noted in guinea pigs exposed at 44.7 mg/m ³ for 5 h or in mice exposed at 40 mg/m ³ for 5 h (Ballantyne and Callaway 1972). Applying a total uncertainty factor of 10 to these concentrations yields a value of approximately 4.0 mg/m ³ for 5 h. One of ten rats died when exposed at 37 mg/m ³ for 5 h (Ballantyne and Callaway 1972). Dividing 37 mg/m ³ by 2 to obtain an approximate threshold for lethality, yields 18.5 mg/m ³ ; application of a total uncertainty factor of 10, yields a value of 1.9 mg/m ³ for 5 h. The values derived from the 5-h data show that the AEGL-3 values are protective.

Footnotes

- 1 This document was prepared by the AEGL Development Team composed of Cheryl Bast (Oak Ridge National Laboratory), Lisa Ingerman (SRC, Inc.), Chemical Manager Glenn Leach (National Advisory Committee [NAC] on Acute Exposure Guideline Levels for Hazardous Substances), and Ernest V. Falke (US Environmental Protection Agency). The NAC reviewed and revised the document and AEGLs as deemed necessary. Both the document and the AEGL values were then reviewed by the National Research Council (NRC) Committee on Acute Exposure Guideline Levels. The NRC committee has concluded that the AEGLs developed in this document are scientifically valid conclusions based on the data reviewed by the NRC and are consistent with the NRC guidelines reports ([NRC 1993](#), [2001](#)).
